Biennial Report of the State Geologist of North Carolina, by Joseph Hyde Pratt, Chapel Hill, N. C. The report is a recapitulation of the work done in 1909 and 1910 on highways, hydrography, forestry, magnetic survey, survey for the North Carolina Fishing Commission, and topographic and traverse mapping of the state.

Report of the Mining Investigation Commission of the State of Illinois to Hon. Charles S. Deneen, Governor of Illinois. The report of this commission covers 68 pages and deals principally with bills revising the laws of the state of Illinois regarding coal mining. It also includes a bill to amend an act entitled "An Act in Relation to Sinking, Filling, and Operating of Oil or Gas Wells," approved and put in force May 16, 1905. It also includes an act to amend an act to require fire-fighting equipment and other means for the prevention and controlling of fires and the prevention of loss of life from fires in coal mines, approved March 8, 1910, and put in force March 8, 1910; also a bill to amend an act entitled "An Act to Establish the Mining Investigation Commission of the State of Illinois, and Prescribing Its Powers and Duties and Making an Appropriation Therefor," approved June 10, 1909, and put in force July 1, 1909.

Annual Meeting of the West Virginia Mining Association, Washington, D. C. Address, Neil Robinson, secretary, Charleston, W. Va.

Iowa Geological Survey, Vol. XX. The annual report for 1909 includes the Geology of Butler County, by Melvin F. Arey; Geology of Hamilton and Wright Counties, by Thomas H. MacBride; Geology of Iowa County, by Stephen W. Stookey; Geology of Wayne County, by Melvin F. Arey; Geology of Poweshiek County, by S. W. Stookey; Geology of Harrison and Monona Counties, by B. Shimek; Geology of Davis County, by Melvin F. Arey. This book can be had by addressing the State Geologist, Des Moines, Iowa.

Mine Rescue Station Commission of the State of Illinois, Report to the Governor and General Assembly of the work accomplished from August 1, 1910, to December 31, 1910, Springfield, Ill.

State Geological Survey, Bulletin No. 16, Oil Resources of Illinois With Special Reference to the Area Outside of the Southeastern Fields, by Raymond S. Blatchley, University of Illinois, Urbana, Ill.

Preliminary Report on the Mineral Production of Canada During the Calendar Year 1910, John McLeish, B. A., Chief of the Division of Mineral Resources and Statistics, Ottawa, Can.

Mineral Production of Ontario for 1910, Bulletin No. 7, Bureau of Mines, Toronto, Ontario.

Department of Mines, Mines Branch, Ottawa, Can. Eugene Haanel, Ph. D., Director, Ottawa, Can. Magnetic Concentration Experiments With Iron Ores of the Bristol Mines, Quebec; Iron Ores of the Bathurst Mines, New Brunswick; A Copper-Nickel Ore From Nairn, Ontario. Bulletin No. 4, second edition, Investigation of the Peat Bogs and Peat Industry of Canada During the Season of 1909-1910, by Aleph Anrep, Jr.

An Act to Consolidate and Amend the Coal Mines Regulation Act and Amending Acts, Bill No. 3, 1911. Address the Minister of Mines, Victoria, B. C.

The Carnegie Foundation for the Advancement of Teaching, Fifth Annual Report of the President and of the Treasurer for 1910. This report may be obtained by writing to The Carnegie Foundation, 576 Fifth Avenue, New York City.

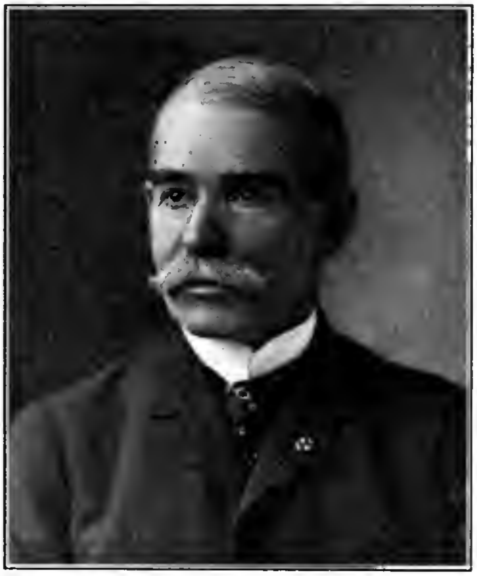
Chrysotile-Asbestos, by Fritz Cirkel, M. E. issued by the Canada Department of Mines, Eugene Haanel, Ph. D. Director, Ottawa, Canada. It contains 300 pages, 66 photoengravings, 88 drawings, two maps of Quebec, and is the only complete treatise on chrysotile, its occurrence, exploitation, milling and uses. It is most practical technical report.

OBITUARY

MAJOR HEBER S. THOMPSON

Major Heber Samuel Thompson, chief engineer of the coal lands of the Girard estate, located in Schuylkill and Columbia counties, Pa., died at his residence in Pottsville, Pa., on Thursday, March 9, in the seventy-first year of his age.

Major Thompson was a lineal descendant of James Thompson, who with his brother John, emigrated from County Antrim, Ireland, and settled at Cross Roads, Chester County, Pa., and was a grandson of William Thompson, who as a young man served as an American soldier in the Revolutionary war. Samuel Thompson, Major Thompson's father, was for many



MAJOR HEBER S. THOMPSON

years a successful hardware merchant in Pottsville, where the latter was born, the youngest of four children, on August 14, 1840. He spent his whole life in Pottsville, except his college years and the years he devoted to the service of his country as a gallant soldier and officer during the Civil war.

His preliminary education was secured in the public and private schools of Pottsville, after which he entered Yale University, where he pursued a classical course. He was one of a large number of patriotic Yale students, who at the outbreak of the war enlisted in the Union army and rendered valuable service to their country. Notwithstanding Major Thompson was in his senior year and within 3 months of graduating, he felt he owed his country his services and enlisted as a private in the Washington Artillerists of Pottsville, and with his company he won the distinction of being among the "First Defenders," or the first troops to reach Washington in response to President Lincoln's call for 75,000 volunteers. While in service, he was granted a furlough to return to Yale, participate in the graduating exercises of his class and receive his diploma with the degree of Bachelor of Arts. Ten years later he received from the same institution the honorary degree of Master of Arts. His first enlistment was, in accordance with the President's call, for 3 months, and he was mustered out of service on July 29, 1861. He reentered the service on October 22, 1861, as First Lieutenant of Company F, Seventh Pennsylvania Cavalry, and on July 1, 1863, he was promoted to the captaincy of Company I of the same regiment.

Major Thompson had an especially honorable career in the war. He participated in all of the campaigns of his regiment,

receiving special mention in orders for distinguished service at the battles of Sparta and Shelbyville, Tenn., Chickamaugua, and Lovejoy Station, Ga. His regiment is classed by Colonel William F. Fox in his "Regimental Losses of the Civil War" as one of the 300 "Fighting Regiments." On March 18, 1864, Captain Thompson was placed on detached service, acting as Inspector General of the First Brigade, Second Cavalry Division, Army of the Cumberland. He was taken prisoner at Lovejoy's Station, Ga., April 20, 1864, released on parole at Charleston, S. C., December 20, 1864, and finally discharged under the General Orders of the War Department, issued January 24, 1865. While still on parole, he was promoted to major, but as he could not take up active service because of his parole, he did not accept the commission.

On his return from the army, Major Thompson, then a young man of 25, felt that with his educational advantages, he was called on to devote his talents to a broader field than was offered by connection with the hardware business established by his father, and then conducted by his elder brother. He accordingly secured a position on the engineering corps of Harris Bros. (a firm composed of the late Stephen and Joseph Harris), at that time ranking as one of the ablest engineering firms in the country.

On the death of Stephen Harris, who for a number of years had engineering charge of the Girard estate, Major Thompson was in 1874, appointed his successor, and he filled the position to the greatest satisfaction of the board of managers of the great charitable trust, and with honor to himself.

An evidence of the responsibility of the position can be shown by the fact that of over 55,000,000 tons of anthracite coal shipped to market from the coal lands of the Girard estate, over 48,500,000 tons were shipped during the 37 years of Major Thompson's service as chief engineer.

As the collieries on the Girard estate are operated by lessees, Major Thompson was not in charge of the actual mining operations, but it was his duty to see that those operations were carried on in accordance with the terms of the leases and in a manner which would conserve the property. In this work he was in constant intercourse with the officials of the Philadelphia & Reading Coal and Iron Co., the Lehigh Valley Coal Co., and other less important lessees, and those officials were always willing to cheerfully accord Major Thompson high rank as an able mining engineer. His work in the construction of water works and the securing of a plentiful supply of water for the collieries, towns, and villages on the estate, marked him also as a civil engineer of high ability.

As a man and citizen the writer's acquaintance with Major Thompson extended over a period of nearly 40 years, beginning when in early boyhood he first met him. To attempt to describe in adequate words his nobility of character, his lovable manliness, his personal integrity, his charity, which not only covered the assistance of the poor, but covered also his personal relations with people of all types, his sympathetic encouragement and assistance to those who needed it to raise them from depths into which they had fallen, and thus enable them to rise to new respectability, and withal his positive convictions on all things he believed to be true and right, and his ability to oppose successfully methods or ideas that were wrong without antagonizing his opponents, but rather increasing their respect for him, would require very much more space than is available in this journal.

Major Thompson at the time of his death was president of the First Defenders' Association, a member of the G. A. R., of the Union Veteran Legion, and of the Loyal Legion of the United States. He was for a number of years president of and a member of the Board of Trustees of the State Hospital at Ashland, Pa., and was also a member of the Board of Trustees of the Pottsville Hospital. He was a member of the county visiting committee of the State Board of Charities and a member of the State Committee on Lunacy. He was also an officer and director of several important local fiduciary corporations.

The scientific and historical societies, of which he was a member, were the American Institute of Mining Engineers, the American Philosophical Society of Pennsylvania, the Historical Society of Pennsylvania, and the Historic Society of Schuylkill County. In religious belief he was a Presbyterian, and was for 37 years an elder of the First Presbyterian Church of Pottsville. His religious belief, while conforming strictly to Presbyterian doctrine, was so broad that he recognized and respected the religious views of all Christian denominations and in his life he made doctrines subservient to true broad Christianity and charity. A true patriot, a consistent Christian, an able engineer, a brave and gallant soldier, who when the war was over held no feeling but that of charity for a defeated foe, he was in fact a man.

SAMUEL F. EMMONS

Samuel Franklin Emmons, geologist, born in Boston, Mass., March 29, 1841, died in Washington, March 28. He received the degree of A. B., Harvard, 1861; A. M., 1866; studied at Ecole Imperiale des Mines, Paris, 1864; Frieberg, 1865; and received the degree Sc. D., Columbia and Harvard, 1909. He was geologist United States Geological Survey exploration 40th parallel, from 1867-1877; geologist United States Geological Survey, 1879; and treasurer National Academy of Sciences since 1902.

His contributions were always welcomed by mining men and geologists, whether they were official reports or written for journals, because of the conscientious way in which the subjects were treated. Few, if any, have done more for the metal industry of the West than the late S. F. Emmons.

DAVID H. MOFFATT

David Halliday Moffatt, banker, died in New York City, March 18, aged 71 years. He was born at Washingtonville, Orange County, N. Y., in 1839.

He became the first cashier of the First National Bank in Denver, Colo., in 1865, and soon after was made president, which position he held until death.

He was one of the leaders in the construction of the Denver & Rio Grande Railroad and was president from 1884-1891. He built the Florence & Cripple Creek Railroad, mostly at his own expense, and at the time of his death was building the "Moffatt" road, to open an important mining area in Colorado. At one time he was largely instrumental in developing Leadville, Creede, Aspen, and Telluride, and while some of his mining ventures were not profitable, others were so successful he was held up as an example by western mine promoters. Dave Moffatt's money, coupled with his mining partner's brains, did much to develop Colorado.

PRICE-PANCOAST MINE HEROES

John R. Perry, miner, and Common Councilman of the First Ward, Scranton, Walter Knight, foreman, and Isaac Dawe, fire boss, died in the Price-Pancoast mine Friday, April 7, 1911. These three men are the heroes who lost their lives attempting to save those of their fellow workmen.

Joseph E. Evans, foreman of the United States rescue car stationed at Wilkes-Barre, Pa., lost his life at the Price-Pancoast colliery fire Friday, April 7, 1911. Mr. Evans was 39 years old, married, and a resident of Scranton, where he was born and respected all his days. He was a member of the Melita Commandery, No. 68, Knights Templar, and was buried by brother knights from his own and other commanderies at the Washburn Street Cemetery, Scranton. Mr. Evans' life is summed up in the words: "Conscientious in all things."

JAMES B. DANIELS

James B. Daniels, manager of the Portland Mills, the man who is said to have given Benjamin and Samuel Guggenheim their first insight into smelting, died at the St. Francis Hospital, Colorado Springs, Colo., April 3. Mr. Daniels was 51 years old and died from the effects of an operation for appendicitis.

CORRESPONDENCE

Clay Shrinkage

Editor Mines and Minerals:

SIR:—It is probably quite incorrect to attribute the settlement of St. Paul's Cathedral, London [see MINES AND MINERALS, March, 1911], to the construction of the tube railways. Nor is it quite correct to describe the London clay as only 64 feet thick under London. The annexed table gives the thickness of this clay at a few places in London. In addition to the London clay proper, there are beneath it certain colored or mottled plastic clays known as the Reading clays, from their development and outcrop near the town of Reading. These clays are variously mottled in different layers of red, blue, purple, yellow, and these colors persist well in dried specimens. Then, beneath the Reading beds come alternations of sand, clays, pebbles, loose and conglomerate, known as the Woolwich beds, and below these comes a bed of greenish sand—the Thanet sand which lies directly upon the chalk. The chalk is the stratum from which most of the many hundred Artesian wells draw their supply in London. Not many years ago some of these actually had a natural overflow. One a few miles out near Wimbledon, drove an overshot waterwheel. That at the Bishop's palace, at Fulham, overflowed. The natural water level of all the chalk water was of necessity once higher than mean sea level. Today it is over 100 feet below sea level, owing to the many years pumping of the many wells, and every year sees an additional foot of lowering, and this is likely to increase until the external hydrostatic head becomes so great that the influx of tidal water, already believed to be in progress, in the east end of London, will become so great as to spoil all the wells, and put a stop to most of the pumping. When this time comes the water level will rise again—it is, and always has been, highest on Monday morning—and the salt water will be pushed out and some wells may be pumped again when this has gone on long enough to discharge the salt. St. Paul's has settled by reason of the shrinkage of the clay beneath it. Arches which run in the crypt from the great piers which carry the dome have sheared off, I am told, some inches vertically because of the greater settlement of the heavier load.

TABLE SHOWING THICKNESS OF STRATA AT VARIOUS PLACES UNDER LONDON

Stratum	General Post Office	Shadwell, East End	Shoreditch, Northeast	Bank of England	Bayswater, West	Oxford Street	Bethnal Green, East	Blackfriars	Chiswell St., City	Cripplegate, East	Fulham, West	Hampstead
	Ft.	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*	*Ft.*
Surface gravel	86	38	18	26	35	33	68	39	26	23	25	
London clay	104		60	111	176	58	68	89	62	71	135	289
Reading beds / Woolwich beds	47	55	40	59	53	55	23	53	89	56	70	40
Thanet sands	62	55	39	39	30	14	43	35	32	16	20	49
Into chalk	388	274	106	100	90	153	166	152	150	110	66	72
Totals	647	419	263	335	389	313	300	368		276	316	450
Surface above O. D.	58			39	87			14		55	15	230

Naturally there was an upward pressure of chalk water below the London clay. Above the London clay there still lies water in the superincumbent layer of about 30 feet of river gravels. Thus the upper clay is still moist; but below, the removal of the deep water, which now probably lies everywhere below or near the upper surface of the chalk, has allowed the whole body of clay and sand to dry out and shrink, and in the writer's opinion, this is the cause of the settlement of the cathedral. Indeed the settlement is much too severe in height to have been quickly caused by the railway work. In driving the tubes of these tunnels the small space behind the cast-iron tubes was very quickly pumped full of grout and the tubes went through very dry clay, as might be seen by watching the carts which carried it away from the shafts. Nor was there any emptying of such a sand pocket as would affect the cathedral. The writer is thus of opinion that the cause must be sought in the removal of upward water pressure and water contact with the sands and clays overlying the chalk. This depletion has been going on many years, but the drying out of the London and succeeding clays only began to operate with serious intensity when this lower surface was left high and dry above water level. The accompanying well records show a curious uniformity in the combined thickness of the Reading and Woolwich beds. The Thanet sand, a seashore sand, thins out in the west and thickens in the east country. About 1,100 feet down, ancient rocks supposed to be Devonian are found. This fact gave rise to the idea that there might be coal under London, or between London and the known coal measures across the sea in Belgium and France. This has since been proved and coal will shortly be raised in Kent.

Thus at 1,100 feet deep the anticipated sequence, as shown by the outcrops to the northwest of London, is missing to the extent of the breadth of the country. London's position was once dry land against which were deposited the lower green sand and other rocks, such as the oolites, new red marls, etc., whilst the Gault clay and the chalk and London clay were laid down at a higher level when perhaps the old rocks had sunk beneath the waves.

W. H. BOOTH, F. G. S.
19 Chatsworth Row, West Norwood, London, N. E.

Size of Shaft Pillar

Editor Mines and Minerals:

SIR:—Is there any rule for finding size of pillars of coal commensurate with the depth of shaft. For instance, a shaft 200 feet deep, 6-foot coal, rock roof, fireclay bottom, has pillars 40 feet wide; under the same circumstances what size pillars would be required for a depth of 400 feet or 600 feet?

W. L. MORGAN

TECHNICAL SOCIETIES

Prof. H D. Easton, Lexington, Ky., has issued a call to the coal operators of Kentucky to meet in conference in Lexington for the purpose of organizing a Kentucky Mining Association. The object of the association is to promote the interests of mining men and improve mining conditions through cooperation in Kentucky. The West Virginia Mining Association was organized three years ago, and is an influential factor in the mining affairs of that state. A similar association in Kentucky would produce more effective results than where individuals act alone. The meeting will take place May 29.

The next and fourteenth annual meeting of the American Mining Congress will take place in Chicago sometime in October, 1911.

The West Virginia Coal Mining Institute will hold their summer meeting June 12, at White Sulphur Springs.

NATURAL GAS LEAKAGE IN COAL MINES

Two coal mines in West Virginia were recently sampled and analyzed for natural gas leakage apparently due to a natural gas well passing through a barrier pillar. Gas was found bubbling up through the water, which, upon examination, corresponded with the natural gas obtained from the well. Samples of mine air vitiated by explosives fired in mines were examined and found to contain in some cases harmful amounts of noxious gases. Samples of natural gas from Nevada were examined, and in one case found to be exceedingly rich in methane. A sample of natural gas obtained from Washington contained 97 per cent. of nitrogen.—*Bureau of Mines.*

THE PRICE-PANCOAST DISASTER

Written for Mines and Minerals

Account of a Mine Fire Which Caused the Death of Seventy-Three Men

The Price-Pancoast colliery which, on April seventh, was the scene of the second greatest disaster in the history of the Anthracite Coal Regions, is owned and operated by the Price-Pancoast Coal Co., and is located in the borough of Throop, Lackawanna County, Pa., about 3½ miles northeast of the city of Scranton.

The coal seams worked are those locally known as the Diamond, the bottom split of the "Fourteen Foot," the Clark, the Dunmore No. 2, and the China seams. All hoisting of coal is done from a four-compartment shaft, 750 feet deep to the Dunmore No. 2 seam. The two end compartments of this shaft are used as upcasts, and there is an exhaust fan 35 feet in diameter on one, and another 20 feet in diameter on the other. In addition there is an exhaust fan 20 feet in diameter on another air-shaft sunk from the surface to the Diamond seam. The downcasts are the two hoisting compartments of the main shaft, the supply shaft, an old slope, and a special downcast located on the hill, some distance from the main shaft and breaker. The accompanying map, which shows the mine workings directly connected with the disaster, shows the main hoisting shaft at A and the supply shaft at B.

The colliery is one of the oldest, largest, and best-equipped mines in the Lackawanna region. Its annual production exceeds 600,000 tons. Besides extensive live workings there are extensive areas of worked-out territory.

The mine is a gaseous one, but with the three fans supplying an aggregate of 365,000 cubic feet of air per minute, and that air conducted through the workings in numerous splits and in a most practical and commendable manner, the gas is so diluted and carried off that open lights are generally used, though safety lamps are frequently used at the working faces, when the amount of gas given off makes their use advisable. The workings in the Diamond seam and the bottom split of the "Fourteen Foot," are practically separate from those in the Clark, Dunmore No. 2, and China seams, and the system of ventilating those workings is separate and distinct from that ventilating the workings in the last-mentioned seams, and is effected by the 20-foot fan on the new air-shaft, which yields over 130,000 cubic feet of air per minute. The coal from these workings is, however, hoisted from the main shaft. There are 400 men and boys usually employed in these workings, and about 500 in the other workings.

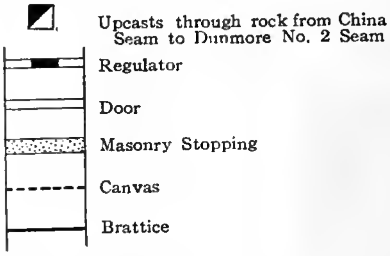
As on several occasions in the past, mine fires of minor importance had occurred through the lighting of blowers of gas, all the working sections of the mine are equipped with a water-pipe line. This pipe line consists of a 3-inch line down the shaft and 2-inch lines into every gangway or main haulage road, with plugs at the entrance of each chamber to which a hose can be attached.

The mine is under the personal direction of Mr. Joseph V. Birtley, general superintendent, and he is assisted by two mine foremen, three assistant mine foremen, and eight fire bosses and assistants. Mr. Birtley has been employed at the mine for over 20 years, by the former owners as general mine foreman, and by the present owners as general superintendent. He is a man of superior intelligence and executive ability and has a deservedly high reputation as a mine official of broad and successful experience.

As the workings affected by the fire were of comparatively limited area, and were in the China seam and connected directly with the Dunmore No. 2 seam only, the map shown herewith, for sake of clearness and because also even a greatly reduced map of all the workings could not be shown on one of our pages, shows only the China seam workings and their connections with the Dunmore No. 2 seam and the main and supply shafts.

The workings in the China seam are shown with solid lines, and those in the Dunmore No. 2 seam with dotted lines.

The course of the air is shown by arrows and the various upcasts to the return air in the Dunmore No. 2 seam, regulators, doors, masonry stoppings, wooden brattices, and canvas sheets, are shown by the following marks:



The mine workings are also equipped with telephones, connected with each other and with a phone in the mine offices on the surface.

All the fatalities occurred in what are known as the Tunnel Workings in the China seam. This seam ranges from 3 feet 6 inches to 4 feet thick and underlies the Dunmore No. 2 seam, with 20 feet of rock between. The China seam is reached by a slope from the Dunmore seam, through rock, and the workings from this slope are at a lower level than the "Tunnel Workings." These latter are reached by a tunnel from the shaft level of the Dunmore No. 2 seam, and as the dip of the seam is only 3 degrees to the north, a main haulage road with a parallel opening runs south, as shown on the map, and from it gangways, as shown, were turned east and west.

On the day of the accident there were 88 men and boys employed in the "Tunnel Workings," 16 of whom escaped, leaving 72 who, with Joseph E. Evans, foreman of the United States Bureau of Mines Rescue Corps, lost their lives.

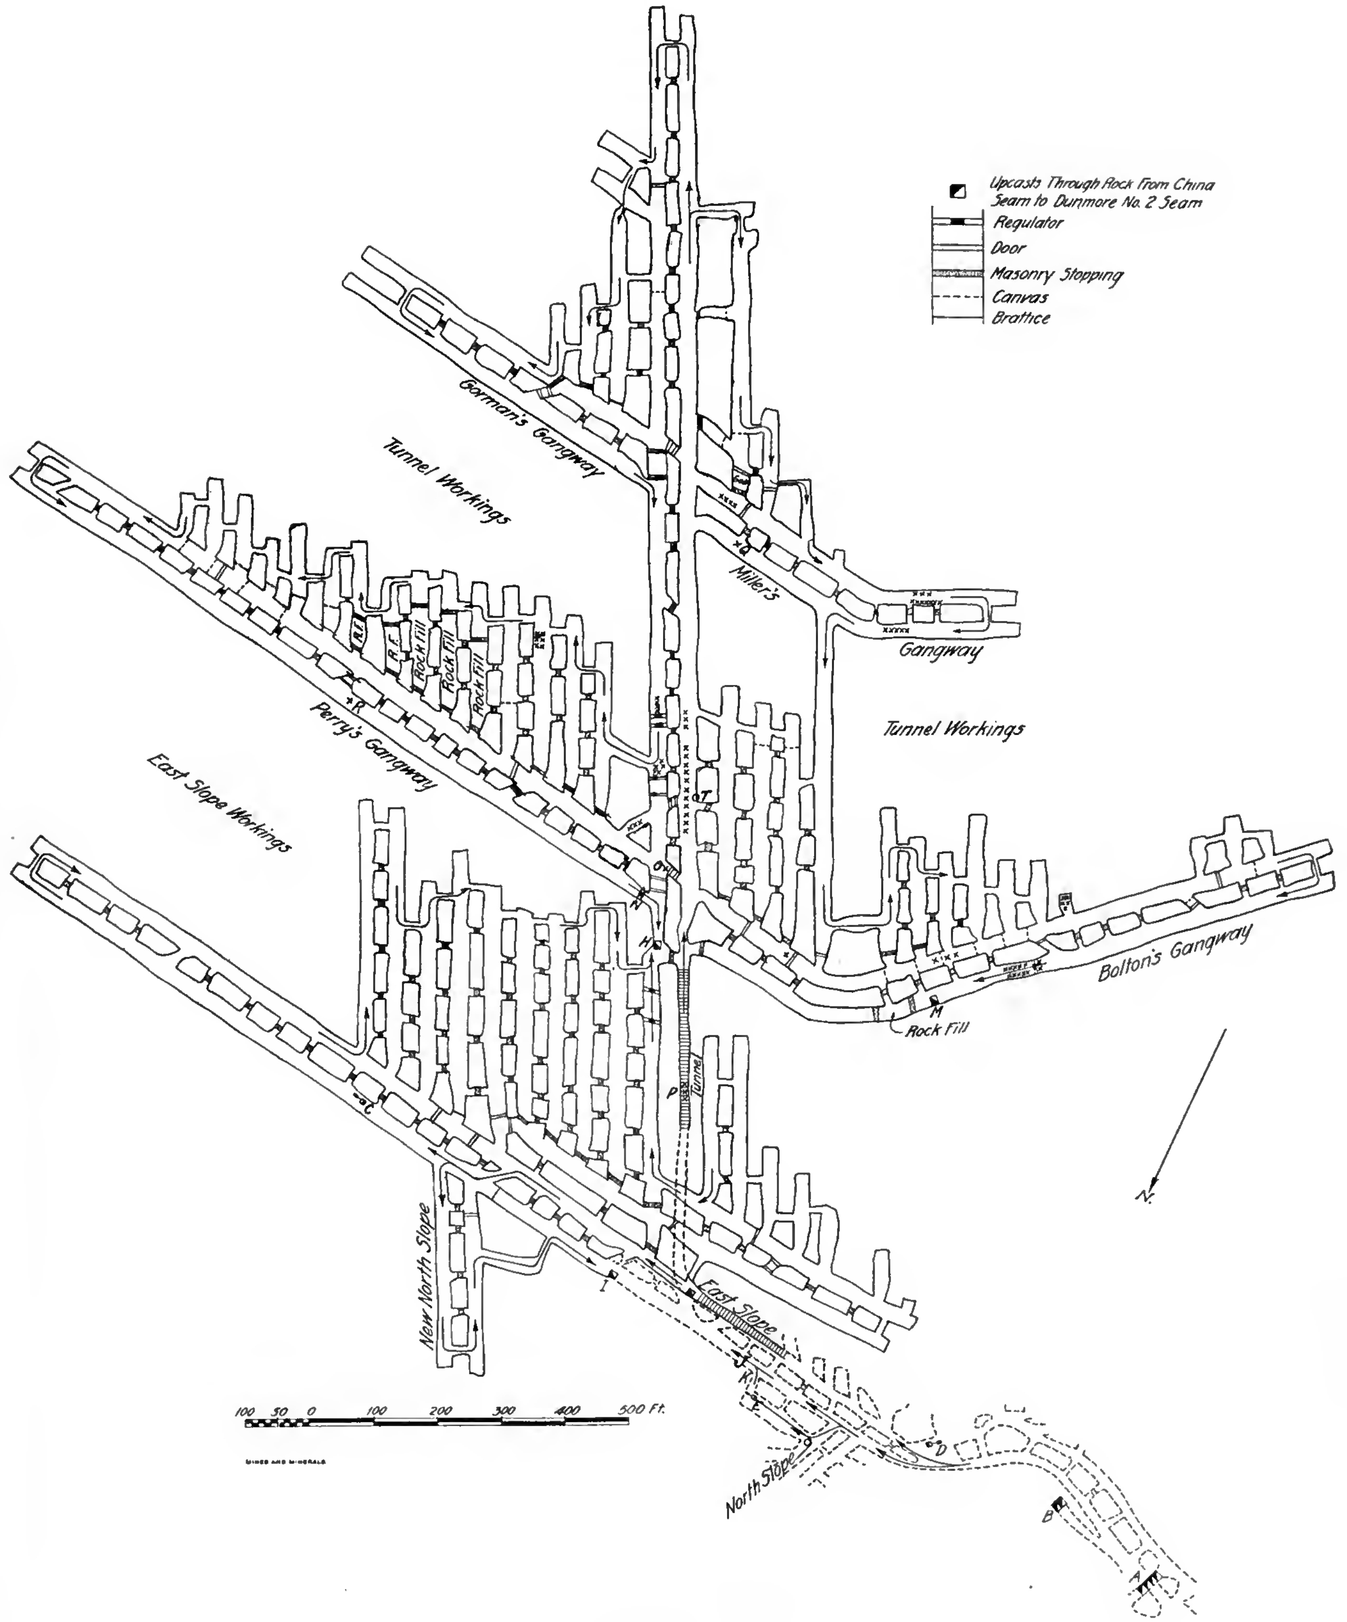
By reference to the map it will be seen that near the main shaft there is a slope in the Dunmore No. 2 seam known as the "North slope," and about 200 yards east of this slope there is one in the China seam known as the "New North slope." These slopes have a dip of from 3 to 5 degrees and are not very long.

As the maximum daily hoist from the "North slope" was but 35 mine cars per day, and from the "New North slope" in the China seam, where rock work only was being done, was 10 mine cars, and as the slopes were not far apart, and the amount of hoisting from both was not enough to occupy a total length of time of 2 hours per day, but one hoisting engineer, James Moran, an intelligent man of about 30 years of age was employed.

The steam for the hoisting engines, C, at New North slope, E, at North slope and the tail-rope engines D, nearer the main shaft, is carried down the main shaft and along the mine passages in well-covered steam pipes, and the exhaust steam from the engines is conducted by pipes to the upcast compartments of the main hoisting shaft.

The engine room E at the North slope is 20 feet long, 15 feet wide, and 7 feet high in the clear. It is cut in the coal and rock, and the roof is supported by sets of 8″×10″ squared yellow pine timbers, each set consisting of two legs and a collar. These sets were from 3 to 4 feet apart. There was also a small wooden platform for the engineer to stand on, and a small closet, or cupboard, in the room. The rope from the drum passed out through the opening shown to a sheave at the head of the slope where it was deflected to the line of the slope. Leading from the drum to the sheave there was a line of planks, under the rope, supported by ordinary mine props from 6 inches to 8 inches in diameter.

The engine room was lighted by a Dietz lantern. This was a large square lantern with three glass sides, containing a tin coal-oil lamp, with chimney, and a reflector back of the lamp to throw the light on the engine and drum.



Map of China Seam Workings, Price-Pancoast Mine

The engines were of the geared type, and, as is usual with this type of engines, considerable oil was used on the gears, and, though the room was kept exceptionally clean, some oil naturally splashed on the timbers.

Shortly after 8 o'clock on the morning of April 7, Moran, the engineer, after hoisting a trip from the North slope lowered the flame in the lantern and went to the New North slope engine, *C*, to do some hoisting there. He had only been there a few minutes when he went back to engine room *E*. In his testimony Moran estimates that he was occupied from 20 to 25 minutes in doing this, and that when he reached engine room *E* he found the interior in flames. A water pipe with a tap was in the engine room and he made an effort to get at it and open it, but was driven back by the flames. He then hurried to the tail-rope engine *D* where there was another tap, opened it, and secured water to play on the fire and called for assistance

William Mitchson, the engineer in charge of the tail-rope engines testified that this was about 8:20 or 8:30 and that he called up six telephone stations in the mine, but got an answer from but one, that in the Tunnel Workings in the China seam shown at *T*. Mike Kozey, the old door man, located near this phone, received the message and immediately started a trip rider named Bray to warn the men in "Bolton's gangway," while he went into "Perry's gangway." Kozey having met Perry and his laborers, left the Tunnel Workings with the laborers and escaped through the slope workings in the China seam. Bray, however, was lost with the seventy-one others.

In the meantime, the air-current used to ventilate engine room *E* carried the flames through the cross heading *K* to 15 empty mine cars standing on the empty track of the turnout *J*. The air-current passing through this turnout is normally about 48,000 cubic feet per minute, and this naturally made the fire more intense.

All this time men were at work endeavoring to extinguish the fire in the engine room, and as they had no possible way to get past or through the smoke, they were not for some time aware of the fire having reached and ignited the mine cars.

Mr. Birtley, when the fire broke out was in his office on the surface, and though not feeling well, was attending to his duties. As soon as he received word of the fire by telephone he went down the shaft, and reached the scene of action a few minutes before 9 o'clock. His first inquiry was whether the men had been notified, and on being told of Mitchson's telephoning, he, knowing the ventilating system so well, knew that all that was possible at the time had been done to warn the men in the Tunnel Workings of the China seam, which was the only section which would receive much smoke, bent all his energies and those of his assistants to extinguish the fire. He soon discovered that the fire was gaining on them and had reached the empty mine cars. Finding that the majority of the men working in the Tunnel Workings of the China seam had not come out, Fireboss Jos. Vickers and Edward Reed started to go in to them by way of the return airway, as it was impossible to get past the fire to go in the intake. In fact, even if they could have passed the fire, the smoke and gas in the intake would have prevented their entering. They had not gone far until they were driven back by the smoke and gas, which by this time was thick in the return air, and Vickers fell. He was taken to the main shaft at once and was with difficulty revived, and later taken to the surface. At the same time a call was made for outside assistance. The local Throop Hose Co. responded and soon had line of hose down the shaft, but as soon as the water was turned on the hose burst owing to the length of the water column. This caused considerable delay, but shortly after noon new hose was in place, and water from the hose and the pipe lines was poured on the fire continuously until about 4 P. M., when it was entirely extinguished.

In response to Mr. Birtley's call for assistance, Mr. C E. Tobey, assistant general superintendent of the D., L. & W. Coal Co., after ordering the Lackawanna company's Rescue Car to the mine, and telephoning Mr. Charles Enzian, superintendent of the United States Bureau of Mines Rescue Station at Wilkes-Barre, of the call, went at once to the assistance of Mr. Birtley. Shortly after he arrived at the mine, he was joined by General Superintendent W. L. Allen, of the Scranton Coal Co. Shortly after 3 o'clock, the D., L. & W. Co.'s Rescue Car, in charge of Harry G. Davis, division superintendent, with a first-aid corps, composed of Wm. White, Lewis Richards, David Bryant, Gwyllim Jones, John Williams, Richard Thomas, and John Driscoll, after a fast run of 25 miles from Kingston, arrived at the mine. This corps was joined at the mine by Ben Hughey, John Fulton, and Alfred Williams, three other Lackawanna men. Mr. Davis and his men brought four oxygen helmets with them, and immediately made preparations to enter the mine. By this time Mr. Enzian, with his corps, accompanied by a Lehigh Valley Coal Co. rescue corps, and two helmet men from the Delaware & Hudson corps, arrived and joined Mr. Davis' party. Among other mine officials who arrived about this time were Gomer Parry, inside foreman of Richmond No. 3 mine of the Scranton Coal Co., and Daniel Young, district superintendent of the same company. Shortly after this, State Mine Inspector Evans arrived, and he was soon followed by State Mine Inspector D. T. Williams. All of these men rendered all the service possible both physically and by consultations and advice.

Shortly after Mr. Davis and the helmet men reached the scene of the fire it was under control, and they were able to get through the slope workings in the China seam to the Tunnel Workings. Mr. Davis, who was unhelmeted, remained in the slope workings near upcast *H* and directed the men in the work. While the D., L. & W. men were entering the affected workings, Foreman Joseph E. Evans, of the United States Rescue Corps, a brother of Inspector Evans, also equipped with a helmet, hurried to join those ahead of him. He entered Perry's gangway through the regulator *N*, and was found sometime later by the returning D., L. & W. men, unconscious at the point *R*. It is supposed that wearing the heavy helmet, he overexerted himself in an effort to catch up with the others and assist in caring for any men who might be alive in the workings, and the oxygen and overexertion affected his heart. Although physicians and first-aid men worked over him for hours he could not be revived. He was a young man of ability, courage, and high ideals, and was the first of the United States Bureau of Mines men to lose his life in an effort to save others.

The origin of the fire will never be positively ascertained, but it is the opinion of the writer that it was caused by the coal-oil lamp in the lantern exploding and throwing burning oil on the dry and oil-bespattered timbers.

The 72 employes in the Tunnel Workings of the China seam were unquestionably killed by carbon monoxide, or "white damp," carried with the smoke from the fire through the workings by the ventilating current. A study of the map and the course of the air will show any one at all familiar with mine ventilation that the main split of the air-current, flowing into the workings through the tunnel and then up the main haulage road to the face where it was split and part conducted through the workings off the Miller and Bolton gangways and part through the workings off Gorman and Perry's gangways, must have first carried smoke on to the men and then some carbon monoxide, which was later increased in quantity when the fire was at its height and large quantities of water were being poured on it. Why all the men did not accept the first indications of smoke as a warning and endeavor to escape, as did the 16 who did get out, will never be explained. John R. Perry, after whom the gangway in which he was working is named, took the smoke for a warning, and with his two laborers went to the mouth of his gangway. Here he met Foreman Walter Knight and Fire Boss Isaac Dawe, who told him they were going in to get the men out, as they realized from the smoke that something

serious was wrong. Perry sent his laborers past the upcast H into the East Slope workings, whence they went in safety by way of the East Slope to the foot of the shaft. Evidently there was then an agreement between Knight, Dawe, and Perry to apportion off the districts each should take. That the quick-acting carbon monoxide was in the air in large quantities by this time is evidenced by the fact that Perry fell and died just inside of the door at O. Dawe's body was found at P, which is the point he reached after probably attempting to warn the men in the workings off Bolton's gangway. Knight's body was found at Q, in Miller's gangway.

Mr. James E. Roderick, Chief of the Department of Mines of Pennsylvania, when notified of the accident, started immediately from Harrisburg and reached the mine early Saturday morning, and Dr. J. A. Holmes, Director of the United States Bureau of Mines, who was in Philadelphia, having heard of the disaster, hurried to Scranton by first train and reached the mine shortly after Mr. Roderick. Both gentlemen joined the other mining men in their consultations and work of rescuing the bodies of the dead. Between 5 and 6 o'clock on Friday evening, Mr. Birtley, who was ill, and who had been working continuously all day, gave out and requested Mr. Allen to relieve him in directing further work for a while, so that he could sit down and rest. Mr. Allen insisted that he should go home and receive medical attention. He finally did go to the surface and to his office where a physician gave him some medicine and advised that he go home to bed. He remained in the office, however, till 9 P. M., when Mayor Von Bergen, of Scranton, with a friend, arrived in an automobile. Mr. Von Bergen, seeing the condition Mr. Birtley was in, practically forced him to go home in his automobile and to bed.

As the fire had been extinguished before Mr. Birtley gave out, the only work to be done was to recover the bodies, and Mr. Allen directed this work. As the ventilation was unaffected, after the fire was extinguished, the gas and smoke soon disappeared and searching parties started the work of looking for the bodies and bringing them out.

The crosses on the map show where the bodies were found, and the locations give evidence that they nearly all tried to escape, but too late. Some bodies were found in positions that indicated death before they realized any danger. In one case a man was seated with his lunch can open and a piece of bread in his hand, as if death had overtaken him while taking a lunch.

None of the bodies showed any evidence of death being caused by any other agent than carbon monoxide, though there must naturally have been enough smoke in the air to render breathing difficult and painful. Some of the men went to the faces of workings hoping, no doubt, to escape the smoke and gas by getting inside the cross-cuts and destroying the brattice, and thus keep the smoke from reaching them. Some took the most natural way of going out the main intake and they of course must have met death very quickly. Others tried the return but were too late, as the deadly gas overtook them. In the case of the 12 men overtaken in the return air-course of Bolton's gangway, 10 had passed through the regulator, and the gas caught them before the two who followed could pass through and close the slide. Had they all passed through and closed the regulator, it is more than probable that they would all have escaped.

Mr. Roderick has expressed an opinion that all the men lost their lives within an hour after the fire started, and the writer after making careful inquiry and examining the statements of survivors and those on the ground, and a careful study of the ventilating system agrees in that opinion.

As usual in the case of large mine accidents the first accounts published in newspapers were inaccurate owing to the haste in which information must be gathered for them. Besides, sensational and demagogical journals, not only had inaccurate statements, but they added to them sensational misstatements that gave the public a wrong impression of the normal condition of the mine and the characters of the mine owners and mine officials.

One false impression created was that the engine house in which the fire started was a flimsy wooden shanty and a fire trap of the worst kind. Instead of being such, it was a room in which an extensive fire would not occur, unless a deliberate attempt was made to start one, or an exploding coal-oil lamp would originate it. Naturally no one would under the circumstances deliberately set it on fire, therefore the exploding lamp theory is most tenable.

Another widely circulated false statement is that there was no second outlet from the Tunnel workings in the China seam. As a matter of fact there were three: one past the upcast shaft H into the East Slope workings, and thence out, and two up the upcast shafts H and M, to the Dunmore No. 2 seam workings and thence out.

Considerable adverse criticism has been made by news writers and others who do not understand mine ventilation and the conditions caused by the fire, that the fans were not stopped as this would keep the smoke and gas from being carried into the China seam Tunnel Workings. Such critics, and many of their readers do not know that if that had been done, the lives of between 400 and 500 employes in the Clark, Dunmore No. 2, and East Slope workings would have been placed in great immediate jeopardy, and besides the smoke and gas would have come back on the men fighting the fire, caused their death or their retreat, and a consequent general mine fire which would have probably cost the lives of several times the number in the Tunnel Workings.

To have reversed the current, as some uninformed writers think would have been advisable, would have brought the fire, gas, and smoke on to the men fighting the fire quicker even than a stoppage of the fans would.

The knowledge that the smoke and gas was being carried into the Tunnel Workings of the China seam was not lost sight of by Mr. Birtley. He knew of a speedy way to cut off the ventilation from that section of the mine, but neither he nor his assistants could get to the proper regulator to effect this, owing to the fire, which was between them and the regulator.

Another criticism on the mine management was that the breaker was operated and coal hoisted for some time after the fire was discovered. In the first place every man in authority on the ground knew that the only men in jeopardy were those in the Tunnel Workings of the China seam, and they thought of nothing else but extinguishing the fire and saving those men if possible. As soon as it was seen that the fire could not be speedily quenched, and that nothing further could be done to get at the men in actual danger, all mining and hoisting was stopped, and all men were ordered from the mine except those actually engaged in fighting the fire and in endeavoring to save the victims.

To sum the whole situation up—here was a well-laid out, well-equipped, and well-ventilated mine, with more than ordinary safety appliances, under the direct supervision of a competent superintendent, who not only knew practically all the employes personally, but who for 20 years had lived among them, shared their joys and sorrows, and who had the respect and good will of all.

A peculiar chain of circumstances, absolutely unforseen, caused the disaster:—A fire that evidently broke out a very few minutes after Moran left the engine room, when he was not there to extinguish it; an otherwise commendable current of air blowing through the engine house, which fanned the fire and carried it through the heading to the empty cars, which were standing in the position provided for them; and an air-current flowing past the burning cars that was so voluminous and well conducted, and which under normal circumstances was a beneficial and healthful agent, but which at this time was turned into an agent of death.

SCRANTON MINE CAVE ENQUIRY

Written for Mines and Minerals

Summary of the Report of the Mine-Cave Commission on Methods of Supporting the Surface

Scranton, Pa., is built over coal beds from which has been extracted, according to the estimates of William Griffith and Eli T. Connor, 198,000,000 cubic yards of coal and rock, or 24,000,000 cubic yards more of material than it is estimated will be excavated from the Panama Canal. The total quantity of coal and rock extracted is estimated at 221,000,000 tons, from which 177,000,000, tons, or 80 per cent. of coal, has been marketed.

It is estimated that the original coal area of 58,110 acres has been reduced by mining to 32,134 acres, which at the present rate of mining, 6,000,000 tons per year, will last 21 years, and if no coal is left for pillars, it will last 31 years.

Messrs. Eli T. Connor and William Griffith, who were appointed by the Mine-Cave Commission to examine the conditions existing under Scranton, handed to the Mayor of Scranton, April 1, a report showing what in their estimation should be done to prevent future mine caves.

The summary of their report follows:

After spending more than 40 days time studying maps and after testing various materials used and considered for the roof support in the mines, and tabulating and considering the information gained by these investigations the conclusions your engineers have reached are as follows:

While some other devices are locally useful, the only method that combines the necessary requisites of strength, ease of application, and reasonable cost, is filling the underground openings by what is known as the flushing method, using for this purpose culm, sand, crushed rock and other fine materials that can be washed into the mines with water.

This method was originated in the anthracite region of Pennsylvania, and has been extensively adopted in European mines, where at great expense, sand, loam, or crushed rock is flushed into the mines following the removal of the coal by the long-wall method of mining.

The tables and estimates of cost contained in the body of the report give in detail the results of our investigations and conclusions. Your engineers, therefore, offer as their only recommendations that the flushing method be adopted, under the plans and specifications, contained in the body of the report and in the atlas before referred to, from which the following general conclusions are drawn:

1. That, speaking broadly, the surface of the city can be supported by the methods recommended, and at a cost not in any sense prohibitory when considered with relation to value of the property and activities for which the support is absolutely essential.

2. That, while there are points in the city, as indicated in the detailed report, where, at the present time, in our judgment, there is distinct and immediate danger to life and property; yet, the total of such area immediately threatened constitutes but about 15 per cent. of the entire area of the city, mainly from surface beds.

3. On the west side the middle series of beds are thick, and close together, and the pillars not columnized, creating a dangerous situation where the workings have not been closed by previous caves. Particular areas thus threatened cannot be definitely specified, on account of the inaccessibility of much of the mined-over area. Detailed investigation should be made of the portions of the mines not already closed. Relatively we do not believe that a large part of the territory mentioned is threatened, on account of so much having been previously closed by caves. Special attention is called to the conditions under schools Nos. 13, 23, and 29. They should be promptly attended to.

The lower series of beds; namely, the three Dunmores, are so thin and so far below the surface that with usual system of mining we do not think they constitute a serious menace to the improvements on the surface except along the margin of solid blocks of unmined coal and near the outcrops. In the deep lying Dunmore beds we believe these solid blocks should be mined.

4. It would seem, therefore, to be not only the part of wisdom, but absolutely obligatory to at once commence to give support to the points menaced, and thereupon proceed upon a general policy of giving support to the entire area of the city; for it must be borne in mind that with the mine activities that are constantly going on, other and additional points of danger are not only liable to, but in all probability will occur with each passing year; it might almost be said, with each passing month.

5. Where the owner of the surface has undoubted rights to support thereof, by coal pillars, in our opinion he could permit the removal of such pillars, and the value thereof would, under average conditions, pay for such artificial support as we have recommended, assuming that the pillars were mined and the support constructed by the same operating company. This observation, however, is based upon the assumption that in such case the operating company is one of the large transportation companies, inasmuch as while there might not be a profit in the immediate transaction of mining the pillars and installing the support, there would of course be a profit to such companies carrying the coal to market.

6. Culm flushing should be used only in coal beds having light cover up to 200 to 500 feet, according to amount of settlement expected, but sand being 4 or 5 times as strong as culm, is best and more suitable for all beds under Scranton and should be preferred.

7. We believe that the conclusion adduced from the tests made, and the calculations and tabulations based thereon, are reasonably reliable; yet, we desire to record the opinion that there are conditions existing in the mines where they might not apply. For instance, in the localities where several seams of coal are separated by a thin stratum of shale and slate, or even sandstone, and the pillars in the two or more seams are not over one another, and it is proposed reclaiming all or any part of the pillars.

Even though an application of the above tables might appear to fit the conditions, we believe that the only permissible procedure would be to first fill with flushed material all of the openings in the lowest vein of the series, and thence upwards, until all are filled, care being taken to have the flushed areas over one another. After all of the openings in all of the seams have been filled, the pillars in the uppermost seam may then be attacked and as each pillar is removed, the space to be at once filled. No pillar reclamation to be permitted in any of the other beds until all of the pillars in the upper bed have been removed and the over burden has come to rest on the flushed material; after which the pillars in the next lower seam may be attacked and handled in like manner.

8. Harmonious plans and procedure between the coal companies, the city, the school authorities, and the public are essential to the successful carrying out of any relief measures that are herein or may be hereafter suggested. It is a fact which should be evident to all that the prosperity of the city and community is to a large extent dependent upon the coal companies, and that drastic laws or regulations that may curtail the mining of coal will necessarily react on the prosperity of the community, and any ameliorating plans or compromises as between the city and the mining companies which it may be possible to effect, tend to prolong the life of the mining industry in Scranton and vicinity, and should be promoted.

It should therefore be the aim of all interested in mine cave protective measures and the companies operating the mines, to adopt plans that will best conserve the welfare of all concerned.

For the business-like carrying out of the plans suggested it is recommended that a protective commission be established,

consisting of not less than three or more than five men, representing the city authorities, school board, and the coal companies; this commission to have full and complete authority for the execution of the plans, approved by the proper legal action.

THE HAZLETON PLUNGER JIG

Written for Mines and Minerals

It has been the custom almost from the time jigs were first installed in the anthracite fields to use those of the pan type, known as the Clark, or Lehigh, jig. Jigs of this description have the bottom of the pan made of wire netting or perforated plates upon which the material to be separated rests and is raised up and down in water.

The principle of this jig, like all other wet jigs, depends for making its separation upon the fact that the coal is lighter than slate and therefore travels farther on the down stroke and falls less rapidly on the up stroke. Thus there is a small movement during both strokes when the coal tends to separate from the slate. But this continued repetition eventually causes the coal to rise to form a top layer, while the slate forms a bottom layer. Ordinarily all jigs in the anthracite field look alike, and the writer's attention was directed to the Hazleton jig by the rotary coal discharge. On further investigation it was discovered that the jig was of the plunger type, that is, instead of raising the pan up and down in water the sieve was stationary and the material resting on it was raised up and down by the movement of a plunger working in water.

While the plunger jig is not a recent invention, nevertheless its adaptation to coal preparation after so many years of the pan jig is something of an innovation.

According to the information given, the plunger jig was first introduced in the Audenreid breaker in 1901, where it was placed alongside one of the pan jigs and made to perform exactly the same kind of work under the same conditions. The result of this comparison for 1 year showed that the cost of repairs for the plunger jig was $10.65, while that of the pan jig was $53.01. This company then adopted more of these jigs, and in the Lehigh region they are becoming popular. Jigs of this description have a large capacity and are capable of treating from 125 to 250 tons, according to the size of the material, per day of 10 hours. In Fig. 1 (*a*) is shown an elevation of the plunger jig and in Fig. 1 (*b*) is shown the plan.

In the figure, *a* is a plunger worked up and down in water compartments by the eccentric *b* on shaft *c*. On the down stroke it forces water from compartment *d* up through a perforated plate *e*, into compartment *f*, and in so doing raises the material resting on the perforated plate or sieve. As the coal is lighter than the slate it travels faster upwards, but when the water recedes as the plunger makes its up stroke the slate falls the faster. Thus separation to a limited extent is produced coming and going.

The material to be treated enters compartment *f* near the sieve through the hopper *g*, then spreads over the sieve as fast as either coal or slate is removed. As the coal accumulates it floats over the gate lip *h*, is scooped up by the rotary-coal discharge *i* and deposited in the chute leading to the pocket. When the slate has accumulated and has become so thick on the sieve as to show signs of running over to the discharge, the doors *j* are opened by the levers *k* to permit the slate to flow into pockets *l*. So fast as the slate accumulates in the pocket it is raised by the revolving buckets *m* and discharged to a chute leading to the slate pocket not shown.

In the Lehigh jig the coal is discharged over a perforated plate which wears out quickly owing to the acid water and abrasion it undergoes. The rotary-coal discharge combines the dewatering part played by the plate of the Lehigh jig; it is also an elevator, thus little water is lost, and in addition, it is said to wear out two sets of plates.

The mud which accumulates in the hutch *n* is discharged by means of the double-gate valve *o* worked by the levers *p*, *q*. However, it may be necessary with dirty coal to entirely draw off the water and sludge in the hutch once or twice daily, and this will necessitate refilling the jig with clean water. A Hazleton jig occupies a floor space of 12 ft. $7\frac{3}{8}$ in. × 8 ft. $10\frac{1}{2}$ in. over all, including the driving gear. To run such jigs requires $4\frac{1}{2}$ horsepower. When working on run-of-mine coal it is safe to assume that from 25 to 50 per cent. refuse goes to the jigs.

Run of mine in this instance means coal that has been crushed to size but not cleaned previous to going to the jigs. The number of revolutions and lengths of stroke given the

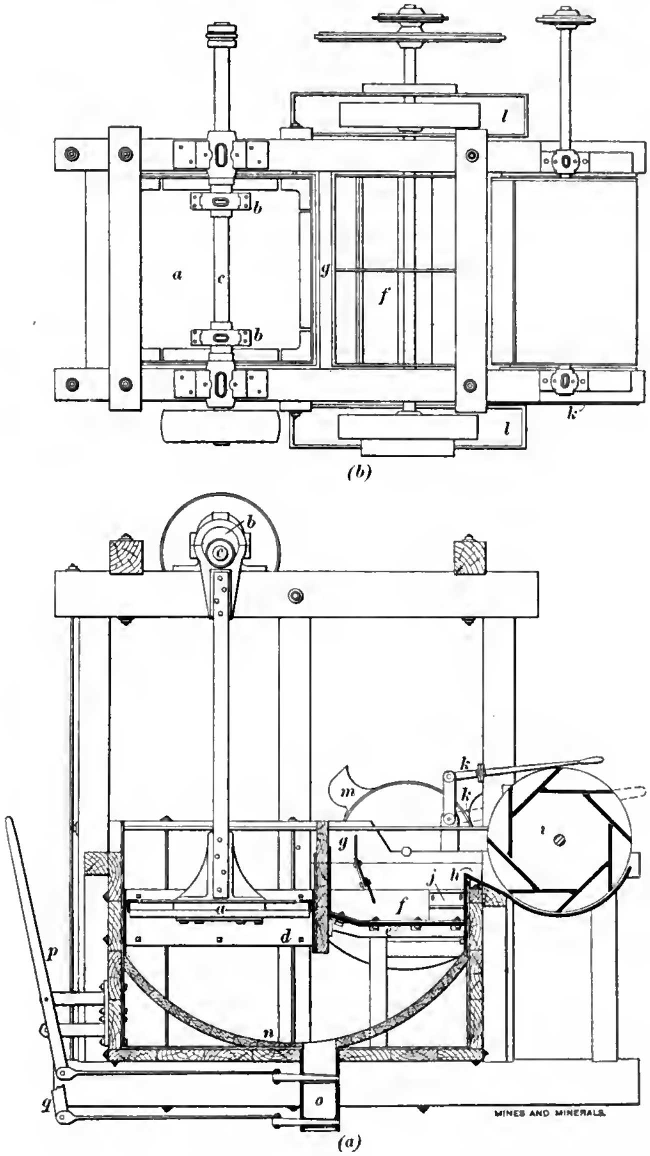


FIG. 1. PLAN AND ELEVATION OF HAZLETON JIG

plunger are determined by the size of material treated. Pea and buckwheat are jigged on strokes $2\frac{3}{4}$ inches and $2\frac{1}{4}$ inches, respectively, at 90 revolutions per minute, while chestnut is given a 3-inch stroke, and egg a 4-inch stroke, at correspondingly lower speeds.

MINE RESCUE CAR SCHEDULE

The following schedule is announced for mine-rescue car No. 2, operating from Trinidad: April 30 to May 10, Starkville; May 11 to 20, Dawson, N. Mex.; May 21 to 31, Raton, N. Mex.

JEFFREY-GRIFFITH CROSS-OVER DUMP

The Jeffrey-Griffith cross-over dump possesses features which differ materially from any dump heretofore described in Mines and Minerals. The claims of the manufacturers are that this dump can be made to work so fast that almost a continuous flow of coal takes place, and they guarantee that it has a greater capacity on this account than other cross-over dumps, besides it has 50 per cent. fewer parts.

In Fig. 1 is shown the dump with the car just entering. The lever by means of which the mechanism of this dump is regulated is shown in Fig. 3. The dump consists of two continuous rails to which are attached substantial horns securely fastened to a heavy shaft. This shaft has a bell-crank and quadrant arrangement with spring securely fastened to one end, while at the other end is located a brake wheel and lever for releasing the car after it has been unloaded. When in operation by the activity of the man in charge and the time it takes for a car to kick back out of the way. It is also claimed that there is less breakage of coal and less wear and tear on the cars. Large dumping capacity such as this is due to the quick and continuous action of the dump, shorter movement of the cars, and the increased safety in bringing loaded cars close to the dumping position.

This is the only dump where the car maintains continuously its natural position throughout the operation. Ordinarily there is a break in the track or the dump is on a pivot. In this case, however, the track is continuous and it is the track horns which move, the car always remaining on the track. When this is understood it can be seen that there is no break or hinge in the tracks which would cause derailment of the cars and that the dump occupies less space than other cross-over dumps, consequently, the cost of the tipple building for a long run to the kick-back is avoided.

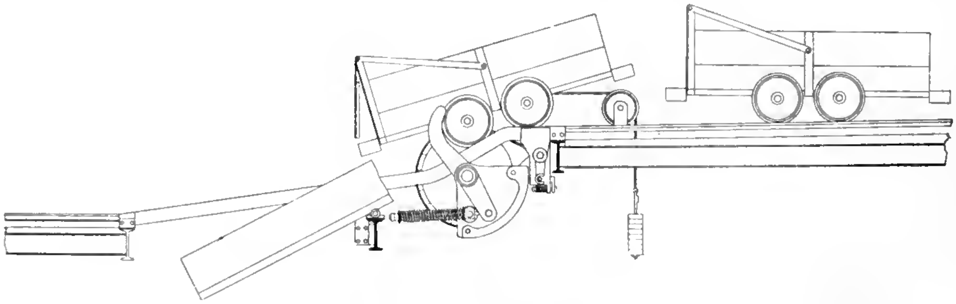

Fig. 1. Car Entering Dump

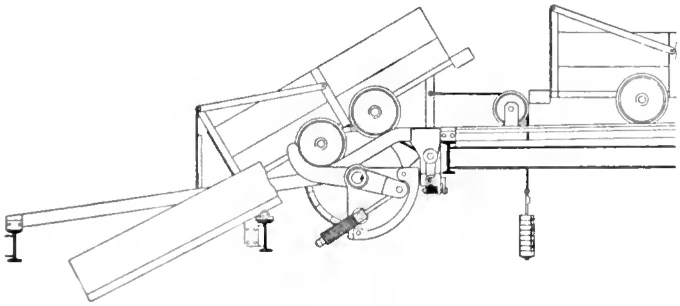

Fig. 2. Dumping

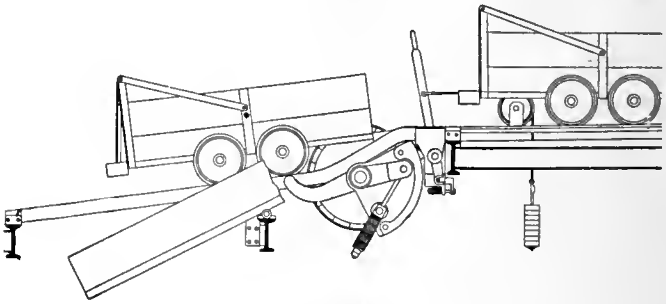

Fig. 3. Releasing

the cars pass on to the dump, as shown in Fig. 1. The impact of the car when it strikes the horns is taken up by means of a spring which absorbs the shock and removes it from the car boxes. One of the most objectionable features to all end dumps has been this shock, which eventually worked the car boxes loose or otherwise injured the car body.

Fig. 2 shows the car in position when it is dumping and is practically a continuation of the movement which occurs when the car runs on to the tipple and strikes the horns. Consequently the front part of the car does not swing and come with a jar against the chute. As soon as the coal is out, the car is released by means of a lever which depresses the horns and permits the car to move over the slightly inclined track, as shown in Fig. 3. There is enough incline to this track to give the car sufficient impetus to run to the kick-back and thence back out of the way of the next car. After the car has passed the horns they automatically resume the position shown in Fig. 1. This is accomplished by means of the spring, which is of sufficient strength to bring the horns into position, together with the rotating action of the quadrant when acted on by gravity. Continuous rails are greatly in favor of this dump, as there is not much likelihood of their getting out of order, besides stoppage of the operation due to derailment of cars is an impossibility.

The manufacturers claim that 10 cars can be discharged over this dump per minute, so that its capacity is only limited

The dump may be seen in operation at the Prudence Coal and Coke Co., Prudence, Tenn. Further details may be had from the manufacturers, the Jeffrey Mfg. Co., Columbus, Ohio.

PERSONALS

W. R. Craig has been appointed acting superintendent of the Shawmut Mining Co., with headquarters at St. Mary's, Pa. Mr. Craig succeeds the late Mr. Ramsey.

W. J. Jones, of Akron, N. Y., has been appointed State Mine Inspector. Mr. Jones was once fire boss at the Red Ash shaft, Exeter colliery, of the L. V. C. Co., and later foreman at the Stevens colliery, West Pittston, Pa.

F. Lynwood Garrison, E. M., Philadelphia, has been examining asbestos deposits in Canada.

James M. Russell, formerly mining engineer with the Development Department of the E. I. Du Pont de Nemours Company has just returned to his office at Deadwood, S. D., after a three months' trip to Arizona, where he examined the property of the Southern Belle Mine for Col. W. F. Cody.

Lewis A. Parsons and John I. Kane, mining engineers, have formed a partnership under the firm name of Parsons and Kane and opened an office at Coles Building, El Paso, Texas.

COAL-DUST EXPLOSIONS

Written for Mines and Minerals, by John Verner

In 1894, after several years investigation of the subject of coal-dust explosions, the British commission presented the following conclusion: "Coal dust alone without the presence of any gas at all, may cause a dangerous explosion if ignited by a blown-out shot or violent inflammation. To produce such a result, however, the conditions must be exceptional and are only likely to be produced on rare occasions." The truth and the significance of this statement is so evident that it seems remarkable that so little has been accomplished in the intervening years to determine the nature of these exceptional conditions. Insufficient investigation in the direction suggested by the British commission is largely responsible for the fact that coal dust is even now considered the most potential and all-important factor in a so-called dust explosion. For many years the investigators of the explosion problem have looked to the dust cloud and followed it as the only guide to lead them to the right solution, but apparently they are still wandering in the wilderness of uncertainty.

Condition and Quantity of Air of Greater Influence on Explosions Than the Dust Content

"As a cause of explosions, I have no faith in the theory of occluded gas; in the distant discharge of explosive mixtures by pressure; in the combustion of coal by friction; or the unknown atmospheres generated by electric current.

"The cause of mine explosions, I believe, are well within the present knowledge of chemistry and physics, but it is the lamentable ignorance in the interpretation of the multitudinous and therefore complicated conditions which exist, each of which, simple of comprehension in itself, but enormously complicated in the aggregate, that has so far prevented a rational explanation of all."

The logic of the above remarks by Mr. Haas is eminently sound. There is nothing mysterious about dust explosions and there is, in my judgment, nothing unexplainable about their occurrence or behavior if cause and effect are properly correlated. In this article I shall advance no new theories. I shall only attempt to present the facts as I have been able to ascertain them through investigations and through comparison of conditions as they existed in mines in which explosions occurred, with the view of establishing their relationship to each other and their mutual effects.

To get first-hand information as to what conditions may develop in the near vicinity of a shot fired in the coal, I made the following experiments in an Iowa mine: The place selected for the experiment was an entry, slightly dipping, 6 ft. × 8 ft. in the clear, its face at a distance of from 60 to 75 feet beyond the last cross-cut. The coal is blasted off the solid and the shots were prepared by the miners working in that entry in the regular way. A few feet inside of the last cross-cut a number of inflated paper bags were suspended by short strings from a collar, a wire was connected horizontally halfway between roof and bottom with the legs supporting the collar, and other bags were suspended from the wire, these bags being about 6 inches from the floor. The observers were stationed in the cross-cut and could readily see any movement of the bags. The experiments were made in still air. The shot fired at the first observation was rather violent, the bags, both upper and lower, were blown outward with considerable force but returned instantly to their original position. Immediate investigation showed no powder smoke along the floor of the entry for a considerable distance inside the cross-cut, and a very rapid air movement along the floor toward the face. Considerable heat was found in the upper part of the entry, especially near the face. The shots at the second and third observation caused a far less violent initial outward force. The paper bags in each case were blown outward, but instantly swung back. Very little air movement along the floor toward the face was noticeable. The degree of heat present was found to be decidedly less than in the first observation.

The shot fired at the first observation plainly showed dangerous tendencies, and it may be reasonably assumed that, with a further increase in heat and flame intensity at the face, as might be produced by a blown-out shot, the force of the outward rush, the consequent instantaneous reaction, and the rapidity of air flow along the floor toward the face, would be increased proportionately. The reaction and the air inflow in the manner stated were evidently caused by the effect of the immediate cooling of part of the heated gases near the face, and the shrinkage in the size of the flame, and by nature's well-known method of action in bringing about the rapid equalization in temperature of contiguous gas bodies of different temperatures. The results developed in the first experiment described above plainly indicate the manner of an explosion's initial start and prove erroneous the generally prevailing theory regarding this process, that the concussion produced by a blown-out shot, or other violent inflammation, stirs up the dust, that the flame projects itself into the suspended dust ahead, keeps on striking into it or impinging on it, and that by this method an explosion is extended as long and as far as there is any dust for the flame to reach. In other words, according to this view, the flame must derive and sustain its vigor by attacking the rear portion of a rapidly receding fuel supply. It seems to me that it must require the absolute disregard of immutable laws and facts to believe that tremendous explosive effects can be obtained under such conditions.

The first effect of the shot in the face of the entry resulted in driving away from the face the air contained in the space near it and with it any dust it might hold. This momentary deficiency in the air supply near the face undoubtedly was a factor in preventing immediate dilution and ignition of some of the combustible gases produced, in diminishing the initial heat intensity, and in reducing the size of the flame, the latter conditions causing an immediate reaction together with a rapid inflow of air along the floor. From this it can be reasonably assumed that, should the fresh air supply along the floor reach the face before the flame is extinguished or the heat becomes too low, the flame will be immediately enlarged, the gases present will be brought to the explosive point and ignited, with the result that the extent of this second inflammation may be far greater than the first, especially if the ingoing air is dust laden. All this will transpire so rapidly that it will be practically impossible to distinguish the second inflammation from the first, except in such exceedingly rare instances as noted in the starting of the Minneapolis mills explosion. It is further evident that the same conditions that influenced an explosion's start, must necessarily obtain in its propagation. The heat and flame area varies in intensity and size during every moment of the explosion's progress; there is a continuous shrinkage and expansion of flame, producing and reproducing with immeasurable rapidity the same effects as at its starting point. It is the presence and influence of this dynamic force that produces high explosive effects, and in its absence the mere contact of flame and coal dust has proved comparatively harmless. The results of experiments and laboratory tests clearly and convincingly show that explosive effects and the propagation of an explosion can only be produced by the forcible injection of air and dust into the flame. Peckham and Peck could only produce explosive effects by blowing the dust into the flame by means of a bellows. In the experiments by Engler, by Holtzwart and Meyer, by Bedson and Widdas, and by Frazer, the dust was ignited by blowing it into the flame by compressed air. Doctor Frazer, in speaking of this manner of producing explosive effects, makes the following remarks of special significance: "Unless there is an exceptionally large amount of dust in the air experience shows that ignition does not take place from a naked flame. This fact is illustrated by the work of Galloway

and that of Mallard and Le Chatelier, who used for the source of ignition different kinds of naked flames, and accords with the conclusions which they reached as a result of their work. It will be recalled too, that Holtzwart and Meyer drew attention to the fact that no ignition was obtained if they introduced lignite dust into their apparatus, and, after establishing the spark between the terminals within, disseminated the dust in the air by shaking the tube. *But when the dust was puffed between the terminals by compressed air, ignition occurred.*"

Under the direction of the Chesterfield and Derbyshire Institute of Engineers "experiments were made in a gallery 82 feet long, 16 inches wide, and 18 inches deep, connected with a chimney to produce an air-current. Coal dust was introduced at the open end of the chamber and carried in by the current. A horse pistol was used to simulate a blown-out shot. The charge was ½ ounce of gunpowder. It was fired into the open end. Out of 134 tests with dust alone, ignition was obtained in 36 cases. Even when 6 per cent. of gas was tried no violent explosion resulted. In the opinion of the observers it was more of an inflammation than an explosion." It may be said that the failure to produce ignition was due to the limited size of the flame produced by the small powder charge, but this cannot be the reason because in the experiments of Peckham and Peck and others a much smaller flame was used as the inciting cause, yet ignition resulted in every instance and with all kinds of combustible dust. The unfavorable results of the Derbyshire experiments can only be accounted for by the fact that the pistol was discharged at the open end of the gallery and that consequently the primary air compression in the gallery from the effects of the shot must have been very small, because the major portion of the pressure produced by the explosion of the powder charge would naturally seek immediate relief through the open end, and therefore the reaction in the gallery was too feeble to carry a propagating supply of air and dust to the flame before it became extinguished.

I believe that the lack of investigation in the past of the value of the air factor, both in a physical and chemical sense, in connection with explosions has been a mistake, and judging from Mr. Rice's remarks in an article on the explosibility of coal dust, it appears that the mistake is to be continued and that investigators have about concluded that everything relating to the air factor has been discovered, making further efforts in this direction useless. Mr. Rice says: "The belief has prevailed very generally among mining men that because a dust explosion is usually manifested in the intake entries the explosion 'feeds on the fresh air' or advances against the air-current. When it is considered that the oxygen content of the return air of the average mine in this country rarely shows a decrease of more than ½ of 1 per cent. of oxygen from the normal, and that the combustion of the coal dust would not be seriously affected unless the deficiency exceeded 2 or 3 per cent. or possibly more, it is clear that there can be little real basis for this impression. In this same connection, the idea has also been expressed that the fan was blowing in fresh air for the explosion to feed upon, and that this accounted for the greater destruction at the intake frequently manifested. When it is considered that the speed of a dust explosion, measured over only a short distance from the origin, as indicated by the Altofts experiments, is 1,400 feet per second, a rate presumably less than when the explosion is under greater headway, and, on the other hand, that the speed of the ventilating current would be at most one-sixtieth part of that rate, it is obvious that the fresh air introduced during an explosion cannot play any part in its propagation, except by the momentary mechanical pressure required to overcome the inertia of the air-current. *The fact that a dust explosion does usually seek the intake entries is due to another cause; namely, that the fresh air has dried the coal dust along the roads, whereas in the return airway of mines of any size the air-current, being saturated with water vapor, has no such drying effect.* The presence of the dust is the all-important thing."

Are the conclusions presented in the above statement warranted by the facts? The mining men may not have stated the case in scientifically correct language when they said that the explosion "feeds on the fresh air," but whether the expression is entirely apt or not is immaterial, the fact remains that it is a fair exposition of the truth. These men based their conclusions on facts as they observed them, they knew that a gob fire with its air supply shut off by brick walls and coal barriers will prolong its existence by crawling toward the tiniest stream of air that finds its way through invisible fissures and will attack the smallest crack in its prison walls in its avidity for more air. They also observed that in case of fierce combustion (and Mr. Rice speaks of "combustion" of coal dust) in a place of rather limited dimensions, like an entry, the fire will advance against the air-current that its effects created or increased. The Delagua explosion is an example of this fact. The truth is that a dust explosion, whether it travels on the intake or the return, or anywhere else in the mine, will always advance against an air-current toward it that must be of sufficient volume and force to sustain intensely rapid and fierce combustion and carry to it an additional fuel supply. An explosion cannot have the weird and uncanny faculty of knowing the existence of the dusty spots and the damp places hundreds and thousands of feet ahead of it, and of chosing its course accordingly. There must be, and there is, a guiding agent.

Mr. Rice's estimate that the difference in oxygen content of the return and intake air rarely amounts to more than ½ of 1 per cent., does not agree with results as I found them. There are many mines in this country where in the winter, the explosion season of the year, the oxygen content of the air on the intake may show an excess over the oxygen content of the air on the return amounting to 5 per cent. and more. I have found temperature in mines below the freezing point at a distance of more than 1,000 feet from the intake opening, while along the return the temperature was in the neighborhood of 60 degrees above zero. No doubt, there are mines, of the Lick Branch mine type, where, under favorable conditions the low temperature zone may be found still more extensive, but with a fairly high temperature prevailing on the return. Supposing that just before the second Lick Branch mine explosion on January 12, 1909, the average temperature of the air in the intake entries near the new mine opening was 32 degrees and that the temperature of the air on the return in the old mine was 60 degrees, then the excess of oxygen content in the intake over that in the return amounted to about 5 per cent. It is true that if 100 pounds of air enter a mine at the intake in a given time, about 100 pounds of air must leave it at the return in the same time and that the effect of air expansion is compensated by an increased velocity, but this is clearly not a question as to how much oxygen passes a given point in a mine in a given time under the ordinary method of ventilation, but a question as to how much oxygen is contained in the different parts of a mine at the moment an explosion occurs and the regular manner of air flow is interfered with.

To illustrate the matter I refer to conditions as they were reported to have existed in the Marianna mine at the time of its explosion on November 28, 1908. The mine was divided in six splits and 190,000 cubic feet of air per minute passed through it just prior to the explosion. The main entries, in groups of six, were driven from the main shaft in opposite directions. The mine was still in a stage of first development and no rooms had been turned. Taken on an average, the faces of all the entries were within a radius of somewhat less than 1,300 feet from either shaft. On account of the large number of parallel entries the linear extent of the excavations amounted to about 25,000 feet. The size of the entries and airways was 9 ft. × 7 ft. The contents of the underground openings were therefore about 1,575,000 cubic feet. Considering the depth from the surface it may be assumed that the normal temperature of the mine would be around 60 degrees, but the latter

being of limited extent and other conditions favorable, it would be readily and materially affected by changes in the outside temperature. Supposing then that on the day of the explosion conditions were such as to cause a reduction of mine air temperature from 60 to 45 degrees, a difference of 15 degrees. This drop in mine air temperature would mean an increase of oxygen content in the mine of 3 per cent. above the normal and it would mean an oxygen increase, measured by weight, of 850 pounds. The explosion traversed the whole mine in a few seconds, and in that short space of time the tremendous energy stored in the additional 850 pounds of oxygen was made available for fiercer combustion and converted into an immensely powerful destructive force. Much has been said about the influence of the presence of a small amount of marsh gas (less than 1 per cent.) in materially contributing to an explosion's development, its extent and force. If the addition of this small amount of gas to the mine air is considered a potential factor, and there seems to be no good reason for doubting the correctness of the claim, the effects on a dust explosion of an increase of the oxygen contents in a mine of several per cent. above the normal must be also of consequence.

By comparing the known conditions of a large number of mines in which explosions occurred, I found that the following features apparently exerted a well defined influence on the magnitude of dust explosions: The thickness of the coal seam, and the number of openings from the mine to the surface with the entries leading from such openings to the mine workings.

In examining the long record of explosions in which coal dust was found to have been a contributory cause, the fact stands out clearly that the most violent and widespread explosions of this kind occurred in mines with coal of fair thickness—6 feet and over—and I have been unable to find any record of a dust explosion in this country in a mine with a coal seam of 3 feet or less. Explosions occurred in mines where the height of the seam was between 3½ and 4 feet, but their violence and extent were comparatively limited and their force was generally confined to the brushed entries. *In a general way dust explosions showed a decided preference for high, narrow entries, and wide rooms were far less affected.* It is but natural that this should be so, for the concentration of heat with a consequent increase in intensity is an essential feature in the propagation of a dust explosion, and the high, narrow entries are of much greater assistance in this respect than the rooms of considerably greater width, that permits the heat and flame stratum to thin out and spread in a lateral direction. In seeking the reason why the most destructive and extensive dust explosions so persistently occurred in mines with coal seams of fair thickness—6 feet or more—and why explosions were less violent and covered less ground in mines with thinner seams, it seems obvious that a difference in dust conditions could not account for it, for the measure of the height of a coal seam does not determine either the dust's quantity or its dryness, fineness, or volatile content. As blown-out shots produce about the same number of heat units per pound of explosive, and as the quantity of explosive used in a shot in the thinner seams is generally as large and often larger than the quantity used in a shot in the thicker seams, it could not be reasonably assumed that the explosive had any bearing in the matter. But when the air conditions were examined the reason for the difference became plain. In a coal seam 6 feet thick, the air content per linear foot of extent of excavation space of equal width is 50 per cent. greater than in a seam 4 feet in thickness, and what is perhaps still more important is the additional fact that the facilities for getting the greater air supply in the thicker seam to the burning fuel are proportionately better than in the thinner seam, and as a dust explosion is primarily a matter of dust combustion, the greater violence and extent of such explosions in thick seams must be due to the greater quantity and availability of the air supply. That appears to be the logical reason and is in full accord with the conclusion by Mr. Haas: *The quantity of air, rather than the quantity of dust or coal is really the measure of the magnitude of an explosion.*

I found further, that the most destructive and extensive dust explosions occurred in mines having more than the usual number of surface openings, with numerous and large-sized entries connecting these openings with the live workings. As illustrations I cite a few well-known cases. The Scofield, Utah, explosion: Two mines connected; four surface openings. The Monongah, W. Va., explosion: Two mines connected; six surface openings. The two Lick Branch, W. Va., explosions: Two mines connected; at least four surface openings. The Darr, Pa., explosion: Three surface openings. The Courrieres, France, explosion: Four mines connected; four hoisting shafts, a centrally located air-shaft, and probably other connections between these mines and the surface. Of course, the connecting of mines increases the territory accessible to an explosion, but the size of a mine alone does not measure the latter's magnitude; for explosions have occurred in dry and dusty mines of considerable extent, yet the territory affected was comparatively limited and their violence correspondingly small. It appears, therefore, that the existence of numerous mine openings and their appurtenances must have an aggravating influence, and, if this is so, again such influence can only be manifested through the action of air and air movements made possible by the presence of these openings.

Before attempting to explain this matter, I will say that coal dust cannot be considered an explosive, in the sense the term is generally used, but, like other finely divided combustible dusts, is readily inflammable, and in my view a so-called dust explosion is really intensely rapid combustion of available fuel, the combustible material affected in a mine ranging all the way from the smallest dust particle to the solid coal. Combustion produced the coking of the solid coal in mines affected by dust explosions (in the Monongah mine the coal was found coked to the depth of 3 inches in places) and consequently in investigating the actions of these explosions, the effects of the influence of the fundamental principles governing combustion should have full consideration. It should also be understood that explosions entirely due to firedamp, and dust explosions, have little in common; they are different in origin, manner of propagation, and effects produced. One point of difference is that in the firedamp explosion there is generally a quite noticeable recoil or return rush due to the rapid cooling of the remaining gaseous content in the territory affected, while in an extensive dust explosion this return rush is almost entirely absent. Many, however, believe in the existence of a return rush of considerable force in the latter case, and the following remarks by Mr. Rice may be taken as expressive of the general view on this subject: "Following such an explosion there is a continued outrush of burned gases, which often carry surplus dust and deposit it on the lee side of projections, sometimes covering the coke just deposited. Succeeding this outrush there is a return rush to fill the vacuum caused by the cooling of the gases. The return wave, if strong, may pick up dust and redeposit on the lee side of projections, or the side which faced the explosion."

Why should the cooling of the gases and the formation of the vacuum be delayed until after the explosion ceases, and what proof is there, for instance, of such delay in the Darr and Monongah cases, where the explosion traversed miles of mine workings and reached the surface? I have no doubt that the tendency toward a vacuum in the rear of these explosions, due to the cooling of the gases and other causes, existed during every moment of their progress, but it certainly did not produce in these instances the effects mentioned by Mr. Rice, either during or after the explosions. If an incipient vacuum back of a dust explosion is not immediately and fully replenished from the rear, then its demands must be satisfied from the opposite direction and in that case an explosion's speed must be affected and reduced, and if this condition continues

or becomes more pronounced, the explosion's forward movement will become slower and slower and may be stopped entirely, notwithstanding the presence of large quantities of dust, and I know from personal experience that explosions did come to a stop in the midst of an abundant fuel supply. It appears, therefore, that the existence of favorable conditions which will facilitate air movements in a mine during an explosion in such manner that they will furnish not only an abundant air supply for propagation, but also for a ready filler to prevent the formation of a vacuum in the explosion's rear, must be of very material influence in assisting the explosion's rapid advance and spread along every available channel in a mine. In this connection the importance and possible influence of the number, size, and location of mine openings becomes apparent. Numerous mine openings, with entries leading from them to the interior workings, will not only aid in developing above favorable conditions in the highest degree, but they will furnish just that many exits for the explosion and permit it to make its attack in quick succession, first in one direction and then in another. In the Monongah explosion there was a proved difference of 5 seconds between the appearance of flame at No. 8 and No. 6 openings, and, as according to the Altofts measurements an explosion travels at the rate of 1,400 feet or more per second, 5 seconds in an explosion represent a lot of time.

Through the courtesy of Mr. Laing, Chief of Department of Mines of the state of West Virginia, I received the following data regarding air movements in mines during an explosion and the force such air movements may develop. When the second Lick Branch explosion occurred on January 12, 1909, Mine Foreman Bowers and another man were within 400 feet of the Tug River opening. This opening is about 5,000 feet southwest of the old mine entrance and about the same distance, in an air line, west of the new mine opening, the old mine and the new mine openings being about 2,500 feet apart. Bowers' first intimation of something being wrong was a blast of cold air coming from the Tug River opening that knocked him down with such force that two of his ribs were broken. Then came a hot blast from the interior of the mine. Bowers, after the explosion, crawled about 200 feet before he was overcome. He was brought out alive and recovered, while his companion, who had been thrown into a ditch and was unable to make any progress toward the outside, was killed. Only on rare occasions can direct evidence be obtained as to what happened in a mine during an explosion, and Bowers' experience, therefore, is of special value, not only with regard to the proof of the air movements, but also because his testimony furnishes a reasonable explanation of the evidence, frequently noted in violent explosions, of severe struggles of forces that apparently moved in opposite directions. Somewhere in that mine there was at least one collision between the cold air blast rushing into the mine with a force sufficient to knock men down and injure them severely, and the explosion, and it can be reasonably concluded that such coming together of opposing forces must result in a fierce and destructive contest.

The occurrence of two very destructive explosions in the same mine, absolutely free from firedamp, well ventilated, and otherwise in good condition, within the short space of 2 weeks is, as far as I know, without a parallel in the mining records of this country and presents in an emphatic manner the valuable lesson that the mere presence of the dust is not the all important factor in an explosion. The Lick Branch explosions occurred in midwinter and both started within a few thousand feet of the intake openings through which large volumes of cold air were drawn into the mine. The latter's oxygen content was undoubtedly considerably above the normal, especially as all the openings were large-sized drifts, driven in a practically level seam, thus making the mine readily responsive to the effects of low outside temperatures. As the coal seam was 8½ feet thick, with good roof requiring no timbering, the mine passages were unusually high and unobstructed. The importance of this feature has already been shown. Looking over the situation as a whole, it appears that these favorable mine and air conditions had vastly more to do with starting and extending the explosions than the dust in the mine, and that the measure of the latter's influence was determined by the former.

A comparison of the Hall tests and the Altofts experiments furnishes further proof that the conditions under which the experiments were made, rather than the dust present, were the more potential factors in determining results. A number of Hall's tests were made in the Big Lady shaft, 630 feet deep. The cannon, charged with 1½ pounds of black powder, was located 540 feet from the surface. If it is true, as claimed, that the amount of dust in suspension measures the magnitude of an explosion, Hall's tests, made in a vertical shaft, under the most ideal conditions of profuse dust suspension should have produced remarkable manifestations of explosive results, yet, he says, there were many failures to cause explosions or to ignite the dust. In one test, admitted to have been the most spectacular of any, the flame filled the pit mouth and ascended 60 feet into the air, but the fact that the flame continued to issue from the shaft for 5 to 6 seconds indicates that the exhibition was really a huge conflagration and not an explosion. On the other hand, in the horizontally disposed Altofts gallery, with the same amount and kind of explosive used, and under far less favorable conditions of dust suspension, violent explosions were produced with unvarying regularity and without a single failure. What caused this difference in results, if it was not the difference and influence of surrounding conditions? If there were exceptional conditions at Altofts, and if the British commission was right that exceptional conditions must exist to cause an explosion in a non-gaseous mine, it is clear that a full explanation and understanding of their character and value must be secured to assure the final solution and settlement of the explosion problem.

There is no lack of measures that have been suggested for the prevention of dust explosions, for limiting their extent, and for providing means of escape for the mine workers after an explosion, but the wide difference of opinion regarding their effectiveness makes it very difficult to decide as to which, if any, of the proposed remedies promises to be of sufficient value to warrant general adoption, and it may help some toward the adjustment of these differences of opinion to examine the more prominently mentioned remedies in the light of the facts obtainable regarding them.

It has been proposed that numerous openings, connecting the mine workings with the surface, be provided in order to limit the extent of explosions and to give the mine workers additional means of escape from a mine should an explosion occur in it. I am of the opinion that their presence in connection with dust explosions will do infinitely more harm than good. There were numerous openings in the Monongah mine and there were many entries leading to them from the workings, yet their existence did not limit the explosion's extent and did not save a single life. There were also numerous shafts and there were many entries leading to them from the workings, yet their existence did not limit the explosion's extent and did not save a single life. There were also numerous shafts at Courrieres, but the explosion in these mines on March 11, 1906, destroyed more than 1,200 lives, and the number of the men who escaped after the explosion was pitifully small. Additional mine openings should be made wherever necessary, for there are other matters to be considered in mining besides explosions, but if they are made, it should be understood that they are not only almost useless as means of escape after an explosion, but that their presence will assist very materially in increasing its violence and extent and thus contribute to the greater destruction of life.

The use of water by sprinkling, spraying, or otherwise is also proposed as a remedy. It looks effective, but neverthe-

less there is a bewildering difference of opinion regarding its value. Some are confident that the application of water is a sure remedy, while others are just as positive in their belief that the presence of water is a detriment and tends to make an explosion more severe, and there are still others with views varying all the way between the two extremes. Proof that the presence of moisture will prevent an explosion under all circumstances is not obtainable, but there is fair proof of cases where the extent of explosions was apparently limited by the presence of considerable moisture or long stretches of water in the roadways. There is also proof that while the presence of water apparently stopped the progress of flame, it did not stop the heated and poisonous gases from passing over and spreading with deadly effect through the mine workings beyond. And again there is still other proof that the presence of considerable moisture neither prevented explosions nor had any appreciable influence in limiting their extent and violence, as the following cases will show. Mr. Newsam reports this instance: A drift opening had been extended 103 yards under ground, wet from the mouth to the face, and water dropping constantly from the roof all the way. There was no gas and no dry dust. The explosion occurred on January 31, 1907. A water car, two-thirds full of water and standing 50 feet from the face, was blown outside and the flame extended 20 feet beyond the opening. The explosion was caused by a blown-out shot, the charge being black powder and the amount less than 3 pounds. The owners of the Vulcan mine in Colorado, desiring to make the mine as safe as possible, installed an elaborate sprinkling system by which it could be kept at all times in a thoroughly damp condition. Along the entries pipes were laid, perforated in such manner that the water in them, forced out under considerable pressure in fine sprays, moistened not only the bottom of the entries, but the sides and roof as well. The owners did not stop with only providing means for keeping the entries saturated. At the mouth of each room was a suitable arrangement to attach to the main supply pipe a hose long enough to reach the room face, and before a miner could fire a shot in his room it had to be made thoroughly wet. As the owners put in this apparatus of their own accord and not because the law required them to do so, it may be reasonably assumed that they insisted on its proper and effective use, yet notwithstanding the mine's moist condition produced by this means, a most disastrous explosion occurred. The mine had been examined and was reported free of gas. Every man in it was killed and the mine itself was almost destroyed. The mine, at the time of the explosion, was of comparatively small extent and well ventilated, between 55,000 and 60,000 cubic feet of air passing into it every minute. In view of the lesson taught by these instances, and others like them could be cited, it is not surprising that men should become skeptical as to the value of the effects of sprinkling or spraying with water. Mr. Payne declares that "coal dust cannot be made wet in the usual sense. The use of fine sprays is indicative of the best results, but even then it is hypothetical if the most careful system of watering is not merely an infinitesimal portion of the ounce of prevention." This view may appear to be rather extreme, but I believe it is very near the truth, and the artificial introduction of moisture in a naturally dry mine, while desirable and beneficial, should not be considered a dependable remedy for the prevention of explosions. Each mine has its own characteristics; conditions differ as between mines, and they may differ materially in the same mine; the power and heat produced by the primary explosion are never the same, and an amount of moisture that may promise a fair degree of safety in one case may be utterly insufficient to give protection in another. It must also be considered that while water may be used in some mines without detrimental effects on the roof and bottom, copious watering may injure others materially and thus create additional danger to the men working in them.

At the Altofts and Lievin testing stations extensive experiments have been and are now under way to establish the value of fine stone dust as a factor in preventing explosions from spreading through the main roads and entries of a mine. I do not know what conclusions have been or may be reached by the investigators as to the value of this proposed means for checking explosions, but I am decidedly of the opinion that in this respect, under the same conditions, the use of stone dust will show far better and more uniform results than the application of water, and that the finer and drier the stone dust the better the results, for the same natural method that propagates and enlarges the flame of an explosion by injecting coal dust into it, must produce the opposite effect by the forcible injection of the incombustible and flame-destroying stone dust; but in either case the influence of extraneous conditions will be a large factor in fixing results. The use of stone dust at the face is evidently not practicable and consequently, while apparently a palliative of considerable merit, it can have little part to prevent the occurrence of explosions in the working places.

The heating of the intake air in the winter and the introduction of steam into the intake are also said to have an influence in the prevention of explosions. On the former proposition Mr. Rice expresses himself as follows: "The plan of merely heating the incoming or intake air to produce summer temperature without introducing additional moisture has sometimes been proposed as a remedy. The fallacy of the argument will be obvious to one familiar with the principles of relative humidity and their application to mine air." It is possible that Mr. Rice was a little hasty in pronouncing judgment. I am fairly familiar with the explosion history of the United States and I know of only one explosion occurring in a nongaseous mine in June, and I failed to discover the record of a single explosion in a mine free from firedamp, that occurred either in the months of July, August, or September during the last 30 years or before. Surely this conspicuous and unvarying absence of dust explosions in the summer time could not have been due entirely to the fact that the air entering the mines at summer temperature always carried sufficient moisture to keep the dust in a thoroughly damp condition. Mr. Haas reports that during 4 weeks in September, 1908, the atmosphere was so dry, according to his calculations, the air carried out of the mines 20 per cent. more moisture than it carried in, representing for an ordinary sized mine a daily loss of about 3,000 gallons of water, and it can be reasonably assumed that there were many instances of long dry spells during the warm seasons of the last 30 years, causing results similar to those shown by Mr. Haas, and yet, under such presumably favorable conditions, not a single dust explosion occurred in a mine, although such explosions have been produced during warm weather under specially arranged conditions in experimental galleries located on the surface.

If Mr. Haas is right, and in my judgment he is absolutely right, that "the quantity of air rather than the quantity of dust or coal, is really the measure of the magnitude of an explosion," then the proposition is equally sound that the quantity and quality of the air, rather than the available fuel supply, determines the magnitude of the initial flame or the initial explosion, and consequently air conditions tending to increase or decrease the size of the initial flame become factors of greatest importance in either promoting or preventing an explosion's start.

It is a well-known fact, that, under the same conditions, with the same air volume entering a mine, the quantity of air contained in the mine, measured by weight, is less in the summer than in the winter, and that in the latter season the oxygen content of the mine may be considerably greater than in the former. Supposing a constant volume of 100,000 cubic feet of air is going into the mine every minute, then with an outside temperature of 25 degrees this air volume carries into the mine about 175 pounds more oxygen than the same air carries into

it in the same time at an outside temperature of 75 degrees, or, in other words, 10 per cent. more oxygen is delivered into the mine under the lower temperature than under the higher, representing an average increase in mine oxygen content of 5 per cent. with the same temperature prevailing at the end of the return in either case. If to a cubic foot of air .07 of a cubic foot of marsh gas is added, the mixture remains below the explosive point, but if the marsh gas volume is increased 5 per cent., or to .0735 of a cubic foot, the mixture becomes explosive, and so it may be reasonably assumed, other conditions being the same, that a 5 per cent. increase of oxygen content in a mine may represent the difference between comparative safety and threatening danger. The heating of the air at the intake in the winter is commendable, because it will at least reduce, if it does not prevent entirely, this oxygen increase and thus create less favorable conditions for the enlargement of the initial flame. If steam is used at the intake the results will be still better, because in addition to its heat producing a decrease in the mine's oxygen supply, the latter will be still further attentuated by the steam itself. Some claim that the greatest value in the use of steam consists in providing a considerable moisture supply. This feature is undoubtedly of benefit, but its value is uncertain, for while there may be a large moisture supply at the beginning, it will gradually become less as the distance from the intake increases and will be very much weakened, if not entirely exhausted, by the time the working places are reached where fresh dust is produced continuously and in greatest quantity and where the danger of its ignition by blown-out shots is the most threatening.

But no matter what remedies may be proposed, the results of their application will remain uncertain and unsatisfactory unless the intelligent and willing cooperation of the mine workers is secured toward contributing their full share in making any of these remedies of positive value, for it will always be true that the safety of a mine primarily depends on the intelligently directed efforts of every individual in it and not on the effects of law enactments or the presence of safety devices. In my judgment the best way to secure such cooperation on the part of the mine workers is by educational methods, by giving them plain and easily understood information regarding the fundamental principles governing explosions and by explaining to them the meaning of the many valuable lessons furnished by mine explosions in the past. These men should have the chance to know the truth, and when they realize to what extent they can promote their own safety, and have the proof to convince them that their help is essential for the benefit of all, they will be intelligently and effectively prepared to give their assistance to the best advantage. The mine workers should be shown that fine and apparently safe mine conditions alone will not prevent the occurrence of dust explosions, and they should know that, as far as these explosions are concerned, large air volumes entering the mines, perfect ventilation, and the existence of numerous openings are not safeguards but, rather, factors of aggravating influence. They should know that the presence of the coal dust is not the all-important thing and that its dangerous characteristics can be developed only by the acts of man and through the influence of other conditions. They must be convinced that the only dependable way to prevent a dust explosion is through the prevention of the initial flame, and while every possible additional safeguard should be provided, it should be impressed on them that their own efforts are of the greatest value and that implicit reliance in the protection of such safeguards or palliatives, whose effectiveness is largely determined by surrounding conditions and may be easily impaired at any time, leads into danger.

Thorough knowledge of the danger incident to his work is the best aid the miner can have in providing for his protection against it, and a moral obligation is resting on the men connected with the coal-mining industry of this country to see to it that reliable advice and information are furnished to enable him to acquire such knowledge in the fullest measure. It was suggested at the Scranton meeting of the Mine Inspectors' Institute of America that the mine inspectors take up this educational work. These men will help wherever they can, but the teaching force is too small; it should include also every mine manager in the United States and every official in the Mine Workers' Union, who may be qualified to assist in the work. If it is profitable for the miners and operators of each state to come together to discuss and adjust wage scales and working conditions, joint efforts by the miners, operators, and mine inspectors for the purpose of investigating and devising means for the prevention of mine accidents will undoubtedly be productive of good results. The plan is feasible and practical it is a humane undertaking in which all should take part, for a united effort in this direction will certainly prove the most potent factor in the preservation of life.

GASOLINE MOTOR HAULAGE

*Written for Mines and Minerals, by Geo. E. Sylvester**

The first furnace south of the Ohio River, to make pig iron with coke as a fuel, was established at Rockwood, Tenn., in 1868. Previous to this time there had only been some small operations using charcoal as a fuel.

Haulage Conditions Under Which Gasoline Motors Show a Saving Compared With Some Other Systems

The locality at Rockwood proved to be well adapted to the establishment of a furnace plant, as the outcroppings of the iron ore, coal and limestone, necessary to the manufacture of iron, were all found within a few hundred yards of the furnace site.

The first furnace was small, and of the hillside variety, with a capacity of 15 tons daily. All pig iron was shipped out, and supplies brought in, by river, 4 miles distant, as there was no railroad through this section at that time.

The plant has been practically rebuilt a number of times since then, and today consists of two 150-ton modern furnaces, shown in Fig. 1, with coal and iron mines, and limestone quarries, necessary for the production of the raw material for the manufacture of pig iron. These furnaces, situated at the foot of Walden's Ridge, have yard connections with two railroads, the C. N. O. & T. P., and the Tennessee Central. The company's main coal mine is located just above the furnaces in the base of the Ridge, the mine extending under the Ridge and the Cumberland plateau to the northwest. This opening was made in 1876, openings having been previously made and worked further up the outcrop to the westward. All of these workings were sooner or later connected, most of the older workings being, however, now abandoned. More than a thousand acres have been covered by these mining operations.

Fig. 1. Furnaces, Roane Iron Co.

The question of haulage has been for a long time a serious problem to the operators of this mine, and to show the difficulties presented it will be necessary to go to some extent into the detail of the coal formation. The coal, which is known as the Sewanee seam, has an analysis as follows:

Washed, Run of Mine

Moisture	.60
Ash	9.00
Volatile matter	32.09
Fixed carbon	57.69
Sulphur	.62
	100.00

It makes a dense hard coke which is exceptionally good for blast-furnace use.

This seam of coal, which outcrops on the face of the Ridge, dips down under the mountain, and is irregular, both in the amount and direction of dip, and in the thickness of the bed. The coal is in pockets separated by barren places, which show only the formation, with from a trace to a few inches of coal, and from which the coal seems to have been squeezed out. These barren territories are, on this account, locally known as squeezes. The coal pockets are often quite large, sometimes many acres in extent, and coal to the thickness of 20 to 30 feet, and even more, is sometimes found. The very uncertainty of the extent and location of the pockets and squeezes, adds difficulty to the proposition of mining.

*Mining Engineer, Rockwood, Tenn.

The mine is worked by a slope about a mile in length, with rope haulage, the maximum pitch being 15 degrees. From this slope there are three main entries, each of which is over 2 miles in length. These entries are driven on a drainage grade of from 1 to 2 per cent., the grade being in favor of the loads. In order to keep the entries on a uniform grade, it was necessary to make them crooked, the miner paying no attention to alinement, but swinging to the right or left to keep on the seam. In running these entries, no attention was paid to whether they ran through coal or squeeze, the object being to develop territory. These main entries present much the same appearance, when shown on the map, as would a wagon road, located with a regular grade, through a mountain section, varying to the right or left to avoid or go around each local hill or hollow.

The entries are from 800 to 1,600 feet apart, most of the local development being made by cross-entries on the pitch of the seam, operated by gravity plane or air hoisting engine, with rope haulage, the general system being such as will work out the coal pockets with as little narrow work in the squeezes as possible. These barren places, being thus left intact, act as extensive pillars, and preserve the mine against any general creep.

The coal is collected to side tracks on the main entries by mules, or by rope from the cross-entries, the nearest point of collection being a mile and a half from the slope.

Mule haulage was formerly employed on these main entries, and it was this long entry haul that presented one of the greatest difficulties in operating the mine.

The total output of from 600 to 700 tons daily had to be hauled from 1½ to 2 miles on these entries, and any trouble or delay at once cut the output for that day below normal.

The management for years has been trying to find some system of mechanical haulage to replace the mules on this entry haul. Electricity, compressed air, and rope haulage, have each been carefully considered; none, however, was found which it was thought would fulfil the difficult conditions presented.

Knowing that the internal combustion engine had been applied to mine haulage in Germany, it seemed that a gasoline mine motor could be made to answer these conditions, but nothing on the market could be found which was adapted to this class of work.

About 2 years ago, learning that the Geo. D. Whitcomb Co., of Rochelle, Ill., were perfecting a gasoline mine motor, the matter was taken up with them, with the result that in April, 1910, one of their motors was installed in the mines.

The results were so satisfactory, that two other motors for the other entries were at once ordered, and were installed in October, 1910.

All the extra work in the mines, necessary for the installation of these motors, was some slight trimming of the rib and top in places, so as to give ample clearance for the motors; and going over the track to replace with 20-pound rail, the places on the entry where a lighter rail had heretofore been used.

There was no difficulty found by reason of the many curves, as the motors have a 4-foot wheel base, and can take a curve

of 25-foot radius. The locomotives are 6 tons each, and were built for the mine gauge of 33 inches. They are designed with 4-cylinder engines, of ample power to slip the wheels, and all parts are well protected, as is necessary for mine use.

The trouble feared was that the gases from the exhaust would be objectionable. This has not proved to be the case however. The motors work on the return air, of which there is from 15,000 to 18,000 feet per minute on each entry, and a

Fig. 2. Trip Coming Out of Mines of Roane Iron Co.

short distance from the motor the fumes from the exhaust are hardly noticeable.

The mine cars used are about 1,400 pounds in weight, and carry $1\frac{1}{8}$ tons of coal. As the grade is in favor of the loads, the empty cars up the entry make the load for the motor. The regular 20-car trips are handled without difficulty, and on trial trips 40 cars have been taken up the entry.

These three motors have already replaced 23 mules; the comparative estimate of mule and motor haulage on one entry being as follows:

Cost of Coal Haul on No. 2 Entry, $1\frac{1}{2}$ Miles or 3 Miles por Round Trip

10 twenty car trips equals		224 tons
By mules:		
4 drivers, at $1.65	$6.60	
9 mules, at $.50	4.50	$11.10
By motor:		
1 motorman, per day	$2.05	
1 coupler, per day	1.65	
13 gallons gasoline, at $11\frac{1}{2}$ cents	1.50	
2 pounds carbide, at 4 cents	.08	
$\frac{1}{2}$ gallon gasoline engine oil, at 23 cents	.12	
1 gallon transmission case oil	.24	$ 5.64
Saving by motor		$ 5.46
Or, 49 1 per cent.		

These motors use 12 to 13 gallons of gasoline each, per shift. The gasoline tanks, of which there are two on each motor, are so placed in the frame as to be well protected in case of derailment or accident. The tank can only be filled when detached from the motor, and in changing these tanks it is necessary to have the valve closed. There are two extra tanks with each motor and these are filled on the outside. When brought into the mine they are perfectly sealed until after being exchanged with empty tanks on the motor. There is therefore no handling of exposed gasoline in the mine.

While these motors require the same care and attention as any similar piece of machinery, the advantage of having a self-contained machine, independent of any other source of power, and ready for use at any time, with nothing to provide for it but the track, is apparent.

POCAHONTAS COAL AND COKE SHIPMENTS

The Crozier Land Co. have issued their 1910 chart of the annual shipments of coal and coke from the Pocahontas Flat Top coal field in West Virginia.

In 1883, the Pocahontas colliery, now the Pocahontas Consolidated Colliery Co., was opened and shipped 60,828 tons of coal and 19,805 tons of coke.

In 1890, there were 16 coal operations which in that year shipped 387,076 tons of coke and 1,808,943 tons of coal.

In 1900, there were 40 collieries in operation that shipped 1,197,294 tons of coke and 4,253,228 tons of coal.

In 1910, there were 69 coal operations that shipped 2,084,023 tons of coke and 10,269,581 tons of coal. Since 1907 the increase of production of Pocahontas coal has been almost at the rate of 2,000,000 tons a year. Since the opening of the field in 1883, 25,231,665 tons of coke have been made and shipped, and 102,767,042 tons of coal have been mined and shipped. The increasing shipments from this field are due to the good qualities of the coal and coke.

Taking the Pocahontas field as a whole, there is not probably another coal field in the world which is so favorably situated for cheap mining. Most of the coal mined up to the present time has been above water level, so scarcely any expense has been required in pumping compared with what is required in other fields where equally good coal exists.

The thickness of the coal bed would probably average 6 feet, and this favors mining. Advantage is also taken of the slight inclination of the coal bed and strata underneath so that loaded trips generally are hauled down grade, while empty trips are hauled on the up grade, which in most cases is very slight, probably a little less than 1 per cent.

During the publicity period when it was necessary to educate people to the value of Pocahontas coal, the selling price of this coal was low. At present, however, the coal is so well established in the markets of the United States that it should bring a price that will be remunerative to the miners.

In some dusty coal mines it is customary to sprinkle the coal with water to prevent dust explosions. It has to

Fig. 3. Whitcomb Gasoline Mine Motor

be frequently repeated, the atmosphere becomes damp, and the mine muddy, and it requires much labor. The Kruskoff process substitutes a paste for water. Coal dries in 6 hours when sprinkled, but remained damp 3,000 hours when treated with this paste. Comparative experiments showed that a dynamite charge of 5 grams produced a coal-dust explosion when water was used, but when the coal was treated with the paste, 12 successive charges of 100 grams failed to produce an explosion.—*Engineering.*

BAILING WATER AT COLEMAN SHAFT

*Written for Mines and Minerals, by F. Ernest Brackett**

During a difficulty with the pumping plant at Coleman shaft, Cambria County, Pa., the local management was forced to try out a pair of 1,200-gallon water bailers, one of which is shown in Fig. 1. A brief review of the matter may be of general interest.

Bailing Skip and Arrangement of Automatically Placed Chutes for Carrying Off the Water

The Coleman shaft, about 660 feet deep, was finished in January, 1909. Considerable difficulty was met in sinking this shaft on account of water. As gauged by the barrel the hoist shaft made during sinking as high as 800 gallons per minute, and the air-shaft added about 350 gallons to this. The maximum water occurring in both shafts simultaneously was about 1,100 gallons per minute. When the shafts were finished the water yielded by both shafts did not exceed 1,000 gallons per minute, and at the time of the trouble with the pump, the shaft and mine water together amounted to about 800 gallons. It may be of interest to know that although during sinking the increased amount of water in the hoist shaft caused the sinking of that shaft to lag behind the air-shaft, which was only about 160 feet away, this fact did not materially increase the water in the air-shaft, or decrease it in the hoist shaft, although as a rule the sand rocks were full of fissures.

The coal at the foot of the shaft dipped at about 2 per cent., the main working being to the rise. A number of drainage plans were discussed before opening the main pump room, but it was finally decided, in order to avoid rock work, to drive a few places in the coal for the sump, far enough to the dip to be below the shaft track system. The pump was then placed about half way between the bottom of this sump and the shaft. To make the suction short, a ditch from 6 to 8 feet deep was dug from the lowest point of the sump back to the pump. The cage pit being lower than the bottom of the sump was drained by a small auxiliary pump. It was the original intention to ditch from the pump room to the cage pit, so that when water reached the main pump level it would flow into the main cage pit. The peculiar contour of the coal, however, made this unnecessary, as the water drained to the cage pit without ditching.

For use in case of a bursted column pipe, or a sudden inrush of water a pair of 1,200-gallon Wellman-Seaver-Morgan automatic water skips were purchased. These are placed on the hoisting ropes after the cages have been removed; the extra length of rope required being provided by attaching an extra piece. Each skip has a pair of automatic door valves in the bottom, which when submerged open inwards by the pressure of the water in the shaft pit. One of these valves is connected by a system of levers inside the skip to a lever at the top of the skip which comes in contact with a striking piece at the top of the shaft, and opens the valve, thus allowing the water to escape. The water chutes at the top of the shaft are arranged to take their places automatically beneath the skip before the discharge gate is opened. Before the skip descends, the chute moves out of its path. These chutes, of which there are two, one for each hoisting compartment, take their motion from the skip by means of a rope connected to a yoke through which the hoisting rope runs, as shown in Fig. 2. By this arrangement in connection with the waterway from the pump room to the shaft, the mine could be unwatered by means of the skips in spite of the entire failure of the pumping plant. The pumps could then be reached from the air-shaft.

At the time of the trouble only one pump had been installed. This was of the triple-expansion outside-packed plunger type, having two water ends and six steam cylinders. The capacity of the pump at full speed is almost 2,000 gallons of water per minute. It formed what the designers considered the first unit of a plant which would ultimately be extended to several units, so that for the time being there was no relief for the main pumping plant except the water skips. There were some quite heavy pumps in the main shaft which had formed part of the sinking outfit, but these had been so far dismantled as to be incapable at the time of the shutdown to handle any considerable amount of the water.

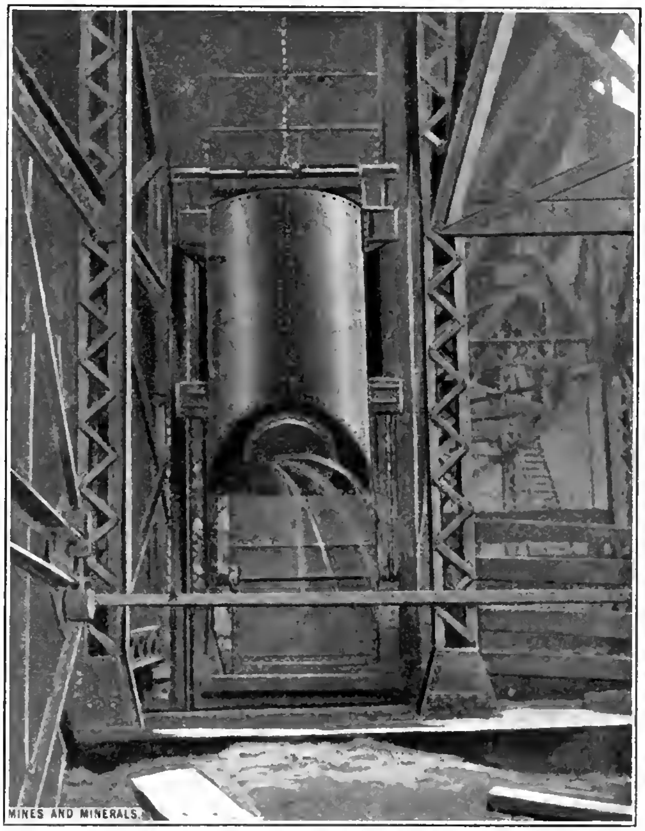

FIG. 1. REAR VIEW OF WATER BAILER

The main pump had not been working properly for several days previous to the shutdown, owing to some obscure trouble with the valve gear. It may be remarked that although the valve gear was by no means complicated, still in a duplex compound pump with 14 rotating valves, where each side drives the valve gear of the other side, and where steam pressures are passed from cylinder to cylinder, and even from side to side, the difficulty in locating valve-gear trouble in a short time is not to be overlooked. There was room for about 8 hours run of water in the sump at the time the trouble began, but between attempts to repair and failure of pump to run properly, the 9th of June found the water up to the pump's steam line leading to the shaft.

The pumpmen remained at work until about 8 A. M., when the steam became so wet that the pump stopped, and the pumpmen narrowly escaped from the room, by reason of the neighboring galleries to the exit being unexpectedly hot from the evolution of steam from the steam line. Probably this trouble would have resulted fatally if the steam line had not been covered with magnesia and tar paper.

Immediately after the pump stopped the timbers used under the cages at the bottom for rests were removed, and the valve at the foot of the shaft in the steam line to the pump was closed. At 10 A. M. the work commenced on the removal of the north cage preparatory to hanging the north water skip. This skip was working at 9 P. M. and water was bailed with it all night. In the morning it was found that the water in the mine had only lowered 3 inches. The second, or south skip was then hung. This occupied from 7 A. M. until 6 P. M., when both

* Civil and Mining Engineer, Cumberland, Md.

skips were working. In hanging the second skip it was also necessary to hang the chute, so that the same work which occupied 10 hours for the north skip, occupied only about 8 hours for the south skip, and the time could probably be shortened further by the careful drilling of men.

On the next day the water had been lowered about 2 feet and the pump room became accessible from the air-shaft. A bucket was attached to the air-shaft hoisting engine, and men were lowered to work on the pump. On June 17 the pump was again started. The bailing of the water in the meantime was carried on intermittently by the main hoisting engine. It was found that bailing from 20 minutes to 30 minutes per hour was sufficient to keep the water down.

When bailing with one skip it was found that a skip of water was delivered every 75 seconds, but by a slight effort a skip could be delivered in 60 seconds. When two skips were in use the time necessary to deliver a skip was from 31 to 38 seconds, averaging 34 seconds. Of this time 20 seconds were occupied in hoisting the skip 700 feet, and the remaining 14 seconds were occupied in slowing down and dumping. The actual dumping only occupied about 5 seconds. The capacity of the two skip hoists was therefore $1,200 \div 34 \times 60 = 2,120$ gallons per minute.

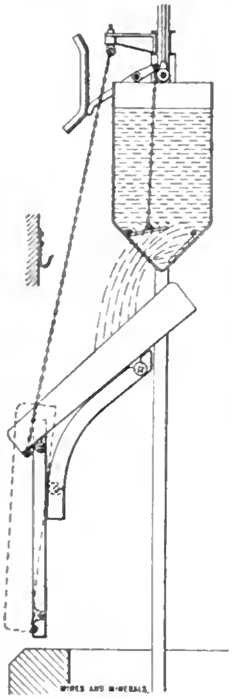

Fig. 2

The amount of coal consumed while hoisting the 800 gallons per minute made by the mine at this time was 23 gross tons per day of 24 hours. It was estimated that 85 per cent. of this, or 19 tons, was consumed in hoisting the water. The consumption of steam by the hoisting engine, as computed from its dimensions was 74 pounds per useful horsepower per hour. As it requires 141 horsepower to hoist 800 gallons per minute 700 feet, the amount of steam required would be 250,416 pounds per day. Dividing the water by the coal, the efficiency of the boilers on this kind of intermittent work is only 6 pounds of steam per pound of coal. The duty of the plant, as computed from the above data is about 15,400,000 foot-pounds of work per 100 pounds of coal, which is extremely low.

From an economical standpoint, therefore, the system of hoisting water in this case is deficient. The economy of the system as here applied was of course only a secondary consideration, but the figures are interesting, as showing what can be done. There are several main causes for this deficiency in economy. In the first place, rapid hoisting on short winds never has been an economical proposition, as there is very little opportunity to use the steam expansively. Even should an attempt be made to do so, the time occupied in getting up speed, when the steam must be admitted at nearly full stroke, occupies a large percentage, sometimes all, of the total time under steam. In the second place, there is a large amount of power wasted during every wind by the application of brakes to bring the load to rest. Besides these, the intermittent use of steam necessarily interferes with the economical operation of the boilers. Enough steam cannot be raised during the demand for it without wasting fuel during the time when there is little or no demand for it.

By careful design, especially on winds of greater length, no doubt these losses can be reduced to some extent, but as a general proposition the plan of hoisting water instead of pumping it should not be adopted, unless there exists some other reason that is of greater weight than the economical side of the question.

Trade Notices

The Chicago offices of the Atlantic Equipment Co. and the American Locomotive Co. have been moved to suite 907-912, McCormick Building, Michigan Boulevard and Van Buren Street.

LeRoy No. 2 mine, at Rossland, B. C., which was damaged by fire about a year ago, is to be reopened. The management would like to receive catalogs of mining and milling machinery for metalliferous mines, also hoisting engines, cables, rope haulage, pumps, machine drills, etc. Address A. Burnett, superintendent LeRoy Mining and Milling Co., Rossland, B. C.

The Sullivan Machinery Co. announces the establishment of a branch office at 35 Federal Street, Boston. Mr. George E. Wolcott, for several years manager of New England sales at the company's Claremont, N. H , office, is in charge and all correspondence shou d be addressed to Boston, instead of to Claremont, in order to receive prompt attention.

Coal operators in Pennsylvania, Ohio, and the northern portion of West Virginia, known as the B. & O. district, will be given prompt and careful attention by directing their inquiries in connection with Goodman haulage and coal-cutting machinery to the branch office of the Goodman Mfg. Co., 2218 Farmers Bank Bldg., Pittsburg, Pa The Pittsburg representation of this company has recently been strengthened by the acquisition of two experienced mining men, Mr. L. F. Crawford and Mr. J. P. Cameron. Mr. Crawford is a man of technical education and training in electrical and mechanical engineering. He has served as superintendent and in other capacities at mines in the West, and has had 6 years experience in the selling and installing of coal-cutting equipment in West Virginia. Mr. Cameron has had varied practical experience in the use of electrical apparatus. He is an expert, particularly in haulage matters. Mr. L L. Brande, long associated with the Pittsburg office of the company, continues as salesman and engineer.

The Boston sales office of the Link-Belt Co., has been moved to more commodious quarters at 131 State Street, Boston. Mr. Lawrence Spillan is in charge.

Large contracts for Garton-Daniels lightning arresters have recently been closed by the Electric Service Supplies Co. with the following companies: Rockford & Interurban Railway Co., Rockford, Ill.; Chicago Railway Co., Chicago, Ill.; Birmingham Railway, Light and Power Co., Birmingham, Ala.; Stark Electric Railroad Co., Alliance, Ohio, and many others.

The Lunkenheimer Company, of Cincinnati, Ohio, has opened a new branch store at 138 High street, Boston, where they are carrying a full line of Lunkenheimer high grade engineering specialties. The store occupies a prominent corner on High street, and is in charge of Mr. Wm. W. Beal.

Simonds & Burns, mining engineers, of New York, have moved their offices to 55 Liberty Street, on the 30th floor.

The Williams Patent Crusher and Pulverizer Co., Old Colony Bldg., Chicago, state that for the first three months of this year their sales of crushers were larger than during any similar period for the last 15 years. They have issued a new catalog describing the crushers which will be sent on application.

The Erdle Perforating Co., of Rochester, N. Y., who have been known as manufacturers of perforated metals for many years have recently made some extensive additions to their plant and are now prepared to furnish perforated metals of all kinds, either heavy or light.

The Sullivan Machinery Co. announces the establishment of an office at 814 Salisbury House, London Wall, E. C., London, England, which will in future have general charge of their business in England and on the continent of Europe. Howard T. Walsh, formerly manager at the San Francisco office of the company, is in charge, and Mr. Arthur F. Belding, recently of the Joplin office, is associated with him.

COAL TRUSTS AND SAFE MINING (?)

Written for Mines and Minerals, by Sim Reynolds in collaboration with W. H. Reynolds

If some man having unlimited time, patience, and means, were to interview in turn every mining official in this country, and request of each his idea as to a perfect, or at least an approximate, solution of our chief mining problems, that man's notes would be the most tessellated writing in all mining literature. Yet each no doubt would be sincere in what he expressed. From our own meagre experience in this direction we can frankly assert that he would get ideas running from a common center to the extremity of right and left angles at least, and some of the extremes would be even more than diametrically opposed.

Not Necessary to Squeeze Out the Small Operators to Ensure Safe Conditions

This much for the proverbial diversity of human opinion, and as a prelude to these few remarks venturing into the lists with Mr. John A. Garcia, Superintendent of the Brazil Block Coal Co., of Brazil, Ind., who in a recent issue of another journal advocated large combinations in coal mining, as a means to reduce the number of accidents.

Our friend finds blood, bone, and sinew awaiting us in the combining of mining operation; i. e., by practically squeezing out the many small operators and giving the control of operation, market, and prices, into the hands of those having unlimited capital to carry out certain methods of mining. The gentleman's solution of our difficulties is, to say the least, ingenious, even if impracticable. He would have us formulate a plan under which certain beds should be won, plans for all mines being suggested along the line of extreme elaboration, which on the face of them would carry a certain elimination of The Great Unfit. And while directly the article in question has reference only to the Illinois and Indiana fields, yet it bears indirect allusion to every coal region in the United States, since what will ultimately prove the solution for one coal-producing area will, modified only by local conditions, prove the salvation of them all.

Mr. Garcia refers particularly to present conditions in Illinois and Indiana, and quotes a mortality list of 213 dead and 874 injured in one year in the former state alone. This, without any extensive and unusual disaster, and for a coal field practically free of the most destructive and subtle agencies of a large mortality (explosive gas, coal dust, and draw-slate) is indeed, to quote from said article, "a pretty bad record," and carries with it a self-evident accusation of grievous carelessness anent the common laws already provided for safe mining in Illinois on the part of the employes, or gross mismanagement on the part of subordinate officials, or both. Apparently the official end is as deep in the mud as the rank and file in the mire, and, as another writer in the same issue of the same journal openly suggests regarding another field, to blame either alone would be simply an obvious attempt to shift responsibility; a case of the pot calling the kettle black. We agree with him that "this looks bad even on paper," but to the man who, being on the spot, sees with his own eyes the terrible results as exemplified in the poor, battered bodies of the dead diggers, and the not less horrible, but even more pitiful, result when the children whom these "dead diggers" cared for in their simple but honest way, are forced out upon the mercy of indifferent strangers, it tells a story of mute tragedy more vivid and fearful than the printed type can ever convey. It does indeed, to quote Mr. Garcia a little further, "bring to the mind of every worthy mining man the flush of sorrow and anger and shame, anger that such things can happen in a country as enlightened as ours, sorrow for the burden-bearers in the form of little children and women folk, and shame that we have not applied the remedy. . ." Aye! there's the rub. What is the remedy? How many who read this would say the same thing? And does not your opinion carry equal weight with mine, all other things being equal?

Mr. Garcia's theory of it is very simple. If it were only as practical! In brief he would, for the Illinois and Indiana fields at least, form plans of safe mining which would involve the outlay of much money. He would have invested in the general or state government the power to close up immediately that mine whose owner had not the means to carry out these safe-mining ideas to the letter. He would extend the same power that now applies to banking institutions to mining of bituminous and other coals. The point is well taken. Certainly the lives of men, and the conservation of vast mineral resources, are as valuable to any nation as the money deposited in bank. If one is deserving of the paternal care of a government why not the other?

With our contemporary's theory we cannot differ, but we strenously object to his method of bringing it into actuality. He would have only those engage in mining whose purses equalled in length and depth their ability and the articles of law. If they couldn't comply "kick them out and keep them out," and leave the production of coal to them who, at any cost whatsoever, would fulfill the law's requirements to the last letter, those who have ample capital to carry out the most elaborate plans of mining, this latter, in Mr. Garcia's mind, evidently being synonymous with safety! This, of course, would remove competition to a large extent, and enable the men engaged to regulate both production and prices concurrent with the necessities of the case. As a matter of fact Mr. Garcia's article is frankly headed "A Remedy for Overproduction," the safe mining being simply the outgrowth of the main issue; i. e., control of the market. In the paper before us, conservation of coal areas and conservation of life seems to us to be merely a bluster for the generic idea, the main line of reasoning seeming to run on the assumption that this admirable arrangement would give the legal status to the removal of wholesome competition in the mining world, and would offer the same reason for the regulation upward of coal prices. If the favored few carried their privilege beyond the bounds of fairness, to again quote the same article, "the Sherman Anti-Trust Law would get them quick!"

What a pity one cannot sometimes set on the printed page a hearty laugh. But while we deprecate Mr. Garcia's knowledge of current events, we sympathize with and commend his frankness. Few men in his position are willing to admit the need of a more strenuous control from the legal side. In fact few of us feel like admitting that there are any serious dangers in the mines we are interested in at all, at all. When serious accidents do occur they are usually at the other fellows' mines, and it is none of our business whether they could have averted them or not. We have enough to do to look after our own. Most mine managers will admit that unnecessary risks are sometimes taken and dangerous methods pursued, that some mines they know ought to be put in a better condition or closed down, and, yet—ask him any way he could make his own mine safer, or reduce the risks his own men are taking, and nine chances out of ten he would be dumb, deaf, and blind. Naturally so. Otherwise he would be in a peculiar position—the case diagnosed, the remedy known, and the doctor admitting he neglected to apply it. And for what reason? Excessive cost? Can we in West Virginia make these changes which mean an era of safer mining if they involve money outlay to any great extent, when over in Ohio they are still trusting to Providence and hammering along in the same old way? While I worked in Pennsylvania I frequently heard the same line of reasoning anent that state and West Virginia. Down here any old chump could open up and run in any old way or no way at all, just so he got out some coal. In common with Mr. Garcia's idea they seemed to think "safe mining" meant altogether an outlay of funds, and an utter impossibility in a stiff competitive market. But is it? We shall see. The same questions have

been asked and answered much nearer the present writers than Chicago is, and answered fairly satisfactorily for a period well nigh on two years, and answered in a manner which gives refutation to the argument that any such revolutionary methods as advocated by Mr. Garcia need be applied. Poor men, or men comparatively poor, have answered them to the indomitable department head's complete satisfaction as well as their wealthy neighbors and competitors in the same field.

For the present, however, we agree with Mr. Garcia that under certain conditions there is a considerable difference in the mine conducted safely and that one run on chance, both in result and cost. Particularly is this so when a mine has been run for a number of years in a happy-go-lucky manner, and then suffered to undergo a complete reformation. But the difference in cost per ton, if taken from the erection of the tipple to the withdrawal of the last chain stump, is not as large as he would have us believe, nor so far beyond the application by the comparatively poor operator, the multitudinous fellow one finds here and there and everywhere over this vast country. There will always be a difference, and a noticeable one, in cost of the total annual output of a mine which has stoppings and overcasts built of brick or concrete and steel beams and masonry, and the same output under less safe conditions in which flimsy brattices of paper-cloth or wood enter. But is the difference all in favor of the latter. Is not the net cost of good work, which means usually safe work, compensation in itself because of the general results accruing therefrom? Does not the cheaply run mine lose almost as much as it gains, if not more? I fancy accurate statistics would convince us that such is the case. Isn't the "cheap" mine management everlastingly trying to patch up this thing and that, or losing time with a breakdown here and a breakdown there, with expense for labor, as well as the result of stoppage of output, running on all the time? Who has not seen the pitiful result of miles upon miles of flimsy brattice (which is one of the greatest factors in safe mining) installed by some manager more economical than wise. A "safe" method does not necessarily imply an extra costly one either at the mine producing 3 flats or at that one producing 50 flats per diem. To make a complete change from the false standard to the true would of course involve considerable extra expense in a large mine, but that would be a miniature revolution, and with revolutions we are not concerning ourselves, but with the steady every-day mining plans in which each day's output stands the cost of that day's expense.

Between the producing costs of the man who does these things with a view to safety and ultimate economy of operation, and the man who dodges both law and necessity for temporary advantage (for the man who does not is either as a rule too dull to know better, or one who knowing better, does not expect to stay "on the job") one would naturally expect a temporary advantage in favor of the haphazard method. But it cannot, according to the law of economics, remain with him. The wooden trestle spanning a periodically turbulent stream may serve the engineering department of an up-to-date railroad for a season, but for making dividends year after year the preference is sure to go in the end to iron, or steel, or concrete, or masonry, with all its additional cost. The difference favoring the haphazard is merely abstract and inconsequential and individual, and not, as Mr. Garcia would have us believe, a fundamental part of the mining industry. The end in either case lies more with the weaver than the fabric. We have known men who could, and did, practically live up to the law's requirements and still produce coal out of the same mine cheaper per ton than their predecessors who had tried to sidestep it.

What we would seem to need more than more combinations of capital or more laws is more mining acumen, more practical ability in the management. An extra hundred dollars a year in this premise quite often leads to thousands in the company's treasury and a better-managed mine. The man who is alive to the economic necessities of an extensive mine is usually a strict disciplinarian, and thus the two essentials of economy and safe operation are found under the same hat. I never yet saw an ill-managed and illegally operated mine that was permanently a good-paying one. The two things are not synonymous at all, or rarely at best. And it is in the "haphazard" operations where the greater part of these single, double or triple fatalities, which run up such fearful totals, occur. A stroke of peculiarly adverse fate, which, like lightning, is apt to strike anywhere, will, sometimes, it is true, work out the same end by destroying the whole mine, such as occurred at several places in our state and other places. But these are the exceptional, and not what our contemporary is hammering at. That we are aware of, there is no evidence of any considerable lack of capital at any of the mines where large disasters have occurred in recent years. And the conservation of life which is being lost day after day, and month after month, by petty accidents due to carelessness on the part of the employes or subordinate mine officials, seems to us to call more for strict discipline in management to remove them than for any such remedy as suggested in Mr. Garcia's article. There is just as much chance for laxity in the million-dollar operation as in that which approximates nothing much more than a country pit. Here is where the elimination of the Unfit would work only good—where general well being would come out of specific sorrow. There are hundreds of mines whose operation is not quite as justified as it might be under just these circumstances, but the several state laws have made provision already for the change, and installed men whose duty it is to close them up. An enlarged capital at any or all of these mines would not imbue these public servants with a greater desire to do their sworn duty. If they are lax now they would be lax then. With good managers and conscientious inspectors they could not remain so. There is no poverty plea which will justify any of them for remaining a menace to human life. In West Virginia, for instance, we have a no small number who would have at some time during recent years been disqualified according to our friend's idea of fitness, yet, Spartan-like they have done their share in upholding the best record in safe mining ever made in this country, or, perhaps, in any other region in the coal-producing world having equal possibilities in the way of wholesale destruction of life. The whole state of West Virginia is burrowed with these "little fellows'" operations, and, almost as one man (or combine) they have shown conclusive proof that a meagre mine treasury is no valid excuse for manslaughter, even though, as was the case with this state a few years ago, they had all apparently been bent on seeing just how near they could skin the lid of Destruction. Evidently they about reached the limit, traversing a distance along that road which every mining man in West Virginia prays they may never reach again. In the entire year just ended, and for a considerable period previous to that, not a single life had been lost from those causes which previous to the present regime gave this region the blackest name in the mining world, and there have been noticeable decreases in the percentages of death and injury from every possible cause. And all this in a field which, taking it in its entirety, has more mines diffusing and making marsh gas and coal dust, not to mention the deadly "draw slate" present over a great part of the region, than any other coal area in the world of the same size. And this, too, in a region where it takes on an average less money to open a mine than anywhere on earth, considering the possibilities of output. How?

Without waiting for the slow action of legislatures, or the rocky possibilities of Federal control, without any wholesale combinations of mining capital, without forcing out of the race the scores of little "fellows" whose bread and butter and permission to mine and ship into the markets of the world was, and is, equally legitimate with their bigger and stronger neighbors, if rightly and lawfully carried out, without any of these things the departmental heads and the operators and managers—

large, medium, and small—reached what might be termed, for want of a better designation, "A Mining Gentlemen's Agreement to Quit Practicing Indirect Murder." In brief, they came to an understanding that each was to mine coal *safely* in the future, along a few simple lines formulated by a committee appointed therefor, each infractor to take what the department had in store for him without squirming. And it was given out quite frankly, and with a determination that left no room for doubt, that these unlegislated agreements would be carried out. Understanding this, everybody went to work to put his several house in the proper order for this new regime. Legislation could come or not, as it pleased. The laws already made, coupled to the amendments agreed on mutually by the mining men of the state, were quite ample, if enforced. It didn't take West Virginia mining men long to find out what was needed, once they got down to rock bottom and started to build a better record from there up, no more than it would Illinois and Indiana or any other field, if they have the grit to enforce what they agree upon. And who is better able to legislate for mining men than mining men themselves, I want to know? Who better understands what we need than we do? What to cut out and what to leave in? There was needed no other sanction than the change in men metamorphosed by their own wills from happy-go-lucky individuals into deeply earnest ones, with a renewed feeling of responsibility to some one else besides their own desire to make money—toward their better selves, for instance, the clear and perfect manhood that is in us all, whether we be delving for coal in Indiana or seeking for diamonds in Africa, toward that clearer perception which sees not only profit but the wife and children in "the mine blocks" beyond the tipple.

With this newer feeling these men went to work to erase as far as possible the bad record The Mountain State had made for herself, hoping by increasing the output and decreasing the death and injury roll to strike a fairer percentage. They started the campaign with the same firm and corporations, the same mines with the same opportunities for death in them, the same unskilled labor, much of it fresh from the vineyards and ploughed fields of Europe. It would have taken a miracle to work up any additional feeling of responsibility toward themselves in these miners, and the result had to be reached through different channels. It had to come, as it did, almost wholly through the men whom the state had given, and was giving as fast as they applied and proved themselves worthy, certificates of competency. The result has been beyond the expectations of the most hopeful among us. And no matter what an adverse fate may have in store for West Virginia in the future, the past year or two will for all time remain like a beacon-light on the sea of mining, pointing to the present and future generations of mining men what men can do when they will, without revolutionary change in the matter of ownership, Mr. Garcia's theory and the results in Indiana and Illinois coal fields to the contrary notwithstanding. It is convincing proof to any one who may be convinced that the means of safe mining lie to a greater extent than is sometimes acknowledged in the hands of the men on the spot—the men in charge—the superintendents, foremen, and fire bosses, and a coterie of public authorities in the mine inspector line, who have a burning desire and the determination necessary to compel adherence to the simple rules for safety. In short, the result in this region is another argument, if any were needed, in favor of intelligent, determined and concerted action as a means to gain any desired end.

MINING AT LETHBRIDGE, ALBERTA

*Written for Mines and Minerals, by A. T. Shurick, E. M.**

Coal mining at Lethbridge is attended with a peculiarly difficult problem due to an exceedingly soft and heavy roof of considerable thickness. This trouble is so pronounced, that before the present system of working was evolved, it was thought the coal could be recovered only by a large number of contiguous shafts of comparatively short life. Since these shafts were of considerable depth and hard to hold, due to the treacherous character of the material sunk in, this proved a serious obstacle to the development of the field.

Fig. 1. Tipple at Colliery No. 6, Alberta Railway and Irrigation Co.

The topography of the zone embracing this immediate district is transitional between mountain and plateau, its salient features being that of broad, gently rolling plains, traversed by streams which have cut deep and relatively narrow valleys.

The surface equipment of the more recently developed mines is modern and complete in every sense of the word. Fig. 1 shows the tipple and head-frame of the Alberta Railway and Irrigation Co.'s colliery No. 6, one of the most recent and probably best equipped plants in the field. The structure is of steel throughout resting on concrete footings, and is equipped with cross-over dumps, shaking screens, conveyers, elevators, and picking belts. All the tipple machinery is electrically driven with the exception of a steam ram for caging the cars; and, following the practice of the modern Pennsylvania breakers, each machine has an individual motor drive. An Ottumwa cradle loader is provided for loading the box cars.

The air-shaft is located close to the main shaft and has a low steel head-frame designed for a man-and-material hoistway. The fan, which is connected to the shaft by a concrete conduit, is a large Sirocco having a rope drive from a pair of Corliss engines; the fan is now being run with one engine, which supplies sufficient air for present needs.

The boilers, hoisting engine, compressed-air and electric-generating machinery are all located in one brick building, shown in the background of Fig. 1. The boilers are Babcock & Wilcox water-tube, equipped with mechanical stokers and ash-disposal system. Ample room has been provided for the addition of further equipment as may be required.

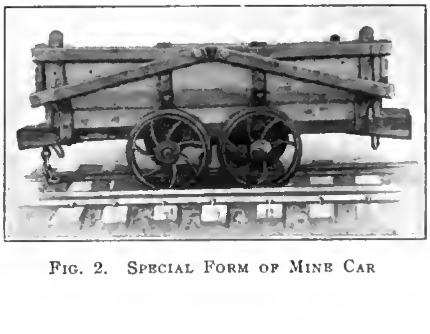

Fig. 2. Special Form of Mine Car

* Engineer Coal Companies' Amalgamated Copper Co., Washoe, Mont.

A feature that impresses the casual visitor is the extreme neatness and excellent manner in which the machinery is kept up; as the writer once heard remarked "you could eat your dinner off the floor any place."

Fig. 2 shows the type of mine car used, which has the rather unusual feature of a door at each end; this is made necessary by the methods of handling the trips underground. The car is low, very strong, and gives excellent service.

The seam lies approximately flat and at a uniform depth of about 500 feet, except in the deeper ravines where the cover is in some instances as thin as 25 feet. Where this latter is encountered, precautions are necessary to provide against inflows of surface water, but since the ravines are relatively narrow these conditions do not often prevail over extensive areas.

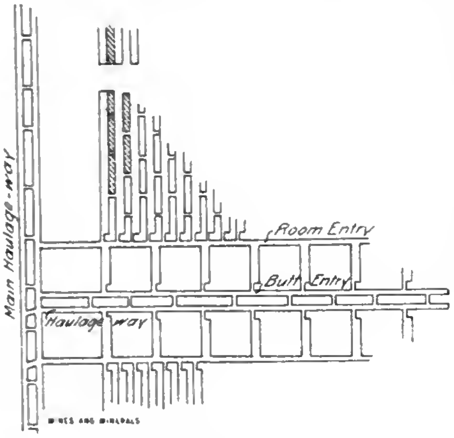

Fig. 3. System of Working

The shaft of the Alberta Railway and Irrigation Co.'s colliery No. 6 is 500 feet deep and equipped for hoisting in balance. Two cars, placed on the cage in tandem, are hoisted at one time, which necessitates a rather large cage and wide shaft. At the present time all the ponies are hoisted at the end of the shift, 2 or 3 ponies and 4 or 5 men to a cage. The ordinary cage, open around the sides is used, and after a few trips the ponies appear entirely unconcerned and indifferent to the experience.

The main haulage underground is usually an endless rope system. Numerous, and occasionally very persistent, faults having a throw of 10 or 12 feet are encountered, which would make the amount of grading necessary for economical electric haulage expensive. Roof conditions are also adverse to such a system. Colliery No. 3 of the same company has one endless-rope system 1½ miles long, the rope traveling the main entry in and back entry out. The rope runs at a speed of about 1.8 miles per hour, the engine being located on the surface and the ropes carried down the shaft. Small ponies are used exclusively to haul the coal to the rope system.

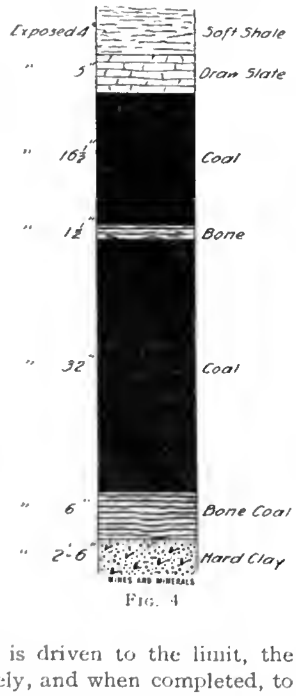

Fig. 4

Fig. 3 shows the generally accepted system of working used throughout the district. The main haulageway is the rope road, and butt entries are turned off this on both sides, with pillars of about 500 feet between. A butt consists of four separate entries, the two center ones being the permanent haulageway while the two outside ones are used as room entries. As soon as a room is driven to the limit, the pillars are brought back immediately, and when completed, to the room entry, the latter is abandoned from there out. This affords a good protection to the permanent haulageway, permits of a maximum recovery of coal, and has been found to be the only system by which the haulageways and airways can be kept open.

Extensive timbering is required on entries that are to be kept open any appreciable length of time, as in the case of the main haulageway. A timber set is made up of 4 pieces, 2 posts and a cap and sill, and on old entries these are almost without exception placed "skin to skin." In the newer workings the sets are placed on from 3- to 5-foot centers.

Fig. 4 shows a typical section of the seam. The soft shale at the top of the section is practically continuous through to the surface and accounts for the existing poor roof conditions. The mining is done in the 6 inches of bone coal at the bottom and shoveled back into the gob.

Ingersoll-Sergeant air punchers are used exclusively for mining. The coal is an excellent fuel, exceptionally hard, as compared with western coals generally, and withstands the deteriorating effects of long exposure with but little loss.

A SECTIONALIZED POWER PLANT

The El Tajo Mining Co., of San Sebastian, State of Jalisco, Mex., recently ordered a sectionalized power plant to supply power for its new mill. The head of water available is 500 feet, and there is a special Pelton waterwheel capable of developing 125 horsepower when running at 1,200 revolutions per minute. With this waterwheel there are two pairs of jaw clutch couplings, to render it possible to disconnect either of the two generators which are to be driven. The waterwheel and the two 50-kilowatt Westinghouse generators are sectionalized for mule-back transportation and no piece weighs over 300 pounds.

These generators are three-phase, 60 cycles, 600 volts and are to run at a speed of 1,200 revolutions per minute corresponding to the revolutions of the waterwheel. They have extended shafts for belt-driving the exciters. The generating station also provides for the usual switchboard, lightning arresters and protection apparatus.

The power generated is to be consumed at the mill by various alternating-current motors, one of which belt-drives the stamp-mill line shaft at a speed of 150 revolutions per minute resulting in the stamps making 100 drops per minute. The tube-mill line shaft runs at 200 revolutions per minute, the mill itself making 37 revolutions per minute. Other motors are scattered about the mill for the usual drives. Since the generating plant is located close to the mill, the generator gives 600 volts and the motors employed are for 550 volts. The lighting is taken care of by separate transformers.

McKeever Bros,. of Philadelphia, are largely interested in this property and the manager of the plant is Robert H. Lilly.

ELECTRIC SHOCK IN MINES

*Written for Mines and Minerals, by Sydney F. Walker**

The question of "earthing" or "grounding" electrical systems in mines has been rather hotly discussed, both in the electrical journals and at the meetings of the Association of Mining Electrical Engineers. It is now very much better understood than it was some years back. "Earthing" was supposed to be taken literally. In America they use a very much better expression, "ground." "Earth" or "ground" was taken literally. It was supposed for instance that if you drove an iron bar into the ground near the face, you made efficient "earth." As a rule you did nothing of the kind. To understand the *rationale* of "ground," it may be as well to refer back to its use in telegraphy and telephone work. It has disappeared from use with the telephone service, because of the interference of messages with each other, which the use of "ground" introduced. This, perhaps, will help to illustrate the difficulty of "earth" in connection with safety from shock in mines. With telegraphs, for instance, where a wire was employed for signaling between New York and Pittsburg, say, the return current was carried back from Pittsburg to New York, and from New York to Pittsburg, by way of the "ground." A connection was made usually to the water service in New York, and to the water service in Pittsburg, and the telegraph currents, which were very small, were allowed to find their way back as they could. In some experiments that were made in the United Kingdom in the early days of the telephone, it was found that the return current from Manchester to London, for instance, sometimes went round by way of Glasgow. For telegraph work it did not matter a bit how the current traveled, so long as the apparatus worked. With telephone work, the "ground" forming the common return, and receiving the currents sent by different subscribers often carried a number of other subscribers' messages to an individual telephone receiver, very much to the user's annoyance. In the very early days of electric light, "ground" was occasionally employed for the return current, but it was only in very rare cases that it could be so used. An instance that occurred in the writer's experience will perhaps illustrate the difficulty. An arc light had been fixed on a dock head, the generator being in an engine house at some little distance. After the light had been at work for some time, it was found necessary to move it farther from the engine, and there not being sufficient cable for the purpose, recourse was had to "ground." One end of a cable was attached to an iron bar and dropped into the dock, and the end of another cable was attached to another iron bar, and dropped into the dock, the circuit being so arranged that the water in the dock formed a part. The light worked fairly well when the dock was full of water, but when the dock was empty, it would not work. The resistance of the damp mud through which the return current had to pass, was so great that the current was reduced below the figure at which the lamp would operate. A similar set of conditions rules in most mines. It is quite easy to obtain good connection with "ground" on the surface. The engines usually make good connection with the ground. The boilers are always connected to some supply of water, which is good "ground" in itself. But when it comes to making "ground" in the mine, it is a very different matter. At the pit bottom there is usually a sump full of water, receiving the drainage of the shaft, and good "ground" can be obtained there. At the face, however, it is almost an accident whether there is good "ground" obtainable or not, and most frequently there is not. In order that good "ground" shall be obtained at the face, it is necessary to make good connection with the ground at the face, and that the electrical resistance offered by the strata between the face, where connection with the ground is made, and the sump or the surface, or wherever the other "earth" connection is made, shall be very low indeed. If the contention of the advocates of armored cable is to hold good, the resistance of the "ground" path must be sufficiently low to pass a current that will operate the circuit breaker, or the fuse, and cut off the cable, when the armor becomes "alive." In the great majority of mines, the electrical resistance of the strata varies enormously.

Importance and Difficulty of Grounding Electric Cable Armor and Apparatus

The investigations into the complaints about the electrolysis of pipes laid in the ground, owing to the stray currents from electrical tramway services, have disclosed the fact that the electrical resistance of the substances forming the earth's crust varies very much. In a great many cases the conducting power is almost directly in proportion to the quantity of water held by the strata. Porous water-bearing strata will have a low electrical resistance usually, while close non-water-bearing strata will have a high resistance. Strata which contain metals will have a comparatively low resistance, and vice versa. The strata themselves vary in the resistance offered. In addition to this, it is a very difficult matter to obtain good electrical connection to the strata. Even with telegraph and telephone work, the obtaining of good "ground" used to be a very troublesome affair at times. In dry weather, for instance, a telegraph apparatus might refuse to work because the connection to "ground" was so bad, owing to the absence of moisture in the soil in which the "ground" plate was buried, that the current necessary to work the telegraph apparatus would not pass. At the face of the coal it is particularly difficult to obtain good connection with the strata. In a large proportion of cases the strata underlying the coal seams are of clay, and clay offers a comparatively high electrical resistance, and is difficult to make connection with. It will be seen from the above how very complicated the question of the use of "earth" or "ground" is, when it is properly considered.

How Ground Protects From Shock.—The principle underlying the protection of men from shock by the use of "ground" is as follows: As stated above, men get shocks when some part of the body touches a conductor, between which and the "ground" on which they are standing a certain difference of pressure exists. The pressure required to kill differs, as already explained, with different subjects, but it is clearly established that a pressure of 150 volts alternating, either between the hands, or from one hand to the feet; or a pressure of 350 volts continuous, from hand to feet, or from hand to hand, will kill. A man receives such a shock, and places himself in a position to receive it, when standing upon the "ground" of a mine road say, or standing perhaps upon the rails, and he touches a conductor forming part of the electrical power service, or having a connection to the electrical power service, as explained above. If all conductors that it is possible for workmen to touch are made to assume the same pressure as the "ground" upon which they stand, it is obvious that shock will be impossible. For instance, the armor of a cable becomes "alive," by making connection with the conductor it is protecting, and if it is at the same time in connection with the "ground" upon which a man is standing he may touch it, but cannot receive a shock. Incidentally it may be remarked here, that it is very difficult indeed, even when good "ground" is obtained, to be sure that the pressure of an armor that has become "alive," is exactly the same as that of the "ground" upon which men in the neighborhood stand. It is usually possible, however, to reduce the difference of pressure between the "ground" and the live armor below the danger point, so that a man who happens to touch the armor, only receives a slight tingling shock that does him no harm.

The difficulty in the way of making the armor always at the same pressure as the "ground" has been explained above, and different methods have been adopted in the United Kingdom for overcoming it. The most promising in the writer's

* Bloomfield Crescent, Bath, Eng.

opinion is one that has been introduced in a large colliery in South Wales. An old wire rope has been carried down the shaft, and along the roads to wherever a cable is fixed, and wherever an electrical apparatus is at work. The armor of the cable is bonded to the old wire rope at frequent intervals, and when falls occur, the armor on both sides of the fall is immediately bonded to the rope. The rope is laid on the floor of the mine, and allowed to make as much connection with the body of the mine as it can. In the particular colliery, it happens to be a very well managed one, there are not many falls, and therefore there are not many cases of broken armor.

Two points are of importance, however, in connection with this matter. Any old wire rope will not do. Mining engineers know that in the older forms of wire rope, in which a certain number of wires were twisted together in one direction to form a strand, and a certain number of strands were laid up together in the opposite direction to form a rope, the individual wires came to the surface of the rope at certain intervals, and as the rope wore they were rubbed through. The consequence was that an old rope was made up of a number of short lengths of individual wires held together by the twist of the rope. Electrically speaking, the only connection between the individual wires was from surface to surface, and as wire ropes are kept well greased, and dirt penetrates to a large extent between the wires, the connection between individual wires by this path was not a good one. The electrical resistance therefore of an old wire rope of that type might be very high indeed, and it was only by using very large ropes, that in the very early days of electric lighting, an eminent mining engineer in the United Kingdom was able to utilize his old wire ropes in place of conductors. The modern forms of wire ropes, however, are very different. In the locked-coil rope, in the rope made on what is called Lang's lay, and in the flattened-strand rope, the wires wear very evenly, and an old rope when it is taken out of service for haulage or winding, will not have a very high resistance, because the individual wires are making good connection with each other, and there are not many wires rubbed through. With old wire ropes of this kind, the plan mentioned above will answer very well, providing that careful connection is made to it. And this is the second point that the writer would desire to call attention to.

Bonding requires to be done with great care. The old wire rope must be cleaned for several inches at least. It should be rubbed quite bright with emery cloth, and all visible dirt removed. Connection to the armor of the cable that is to be "grounded," or to switch boxes, etc., may be made either with a copper or an iron wire. A copper wire will be best, because it can be more easily wrapped around the wire rope, and around the armor, but where copper wires are used, the bondings should be inspected from time to time, as electrochemical action will be set up between the copper and the iron, tending to destroy the connection. A copper wire also will answer better because it has a lower resistance than an iron wire of the same size. In either case, whether a copper or an iron wire is used, it should be wound very tightly around the wire rope for 2 inches or more, and the armor of the cable should be treated in exactly the same way. It should be cleaned, and the bonding wire should be wrapped around it for at least a couple of inches. It is of importance that all switch boxes, distribution boxes, electric-motor cases, and any pipe or fitting that is used to protect wires, lamps, or other apparatus, should also be connected to the "ground" cable. The connection can be made in the same way, by wrapping a wire around the old wire rope, but connection to the switch boxes, etc., should be by means of large flat-headed screws, that can be well tightened down.

In another colliery in South Wales, another method has been adopted. Falls are provided against by building stone walls along the sides of the roads where cables are to be placed, the walls being of sufficient strength to support the roof under all circumstances, and to withstand the squeeze. A ledge is built in the wall, under which the cable is held upon an insulator, so that any squeeze which comes upon the wall, and which might possibly tend to grip the cable, is held off by the special shelf provided for it. In this colliery also, a "ground" wire is provided by a galvanized single strand wire, carried to the neighborhood of all the cables, and all the apparatus supplied by them. In the writer's opinion, it is doubtful if the single-strand wire would answer its purpose under all circumstances. The "ground" conductor, whatever form it may take, must have a sufficiently low resistance to allow any leakage current that passes out of any one of the cables to return to the generator without an appreciable difference of pressure arising in the "ground" conductor itself. If the "ground" conductor has a high electrical resistance, a difference of pressure may exist at certain parts of the mine between armor, switch boxes, etc., that are supposed to be "grounded" and the "ground" itself.

"Grounding" With Three-Phase Services.—"Grounding" with three-phase services is a rather different matter to that with continuous current. Star-connected generators and motors are usually employed in mines, and the neutral point of the star, the common junction of the three coils of the generator and motor, are connected to "ground." The same idea rules; viz., that if the armor of the cable becomes "alive" the circuit breaker or fuse will cut it off, and the armor itself being connected to "ground," a man cannot receive a shock from it. Provided that the armor is bonded everywhere to a good "ground" cable of low electrical resistance, this is nearly always quite correct. Peculiar cases arise, however, with three-phase services, in which "grounding" of the neutral may lead to conditions under which a shock may be obtained. Thus, if a motor stands upon stratum that offers a high electrical resistance, its case being connected to the "ground" cable, and a leakage occurs on one of the phase cables, it will be possible for a man touching the case of the motor to receive a shock. The conditions here are really inverted. The leakage from one of the phase cables has made the "ground" at a different pressure from the "ground" cable, and the case of the motor being connected to the "ground" cable, a difference of pressure exists between the case of the motor and the "ground" upon which it stands, and consequently a man touching the case of the motor bridges this difference of pressure, and may receive a shock. This will perhaps illustrate forcibly the great difficulty of the problem involved, and may lead mining engineers to understand why the present writer has always so strongly advocated insulation of every electrical apparatus about a mine before all things. If generators, motors, cables, switch boxes, etc., are insulated from the body of the mine and from every conductor about the mine, and if the insulation is maintained at a high figure, it will be very difficult indeed for anybody to get a shock. His view is, that with continuous currents, if one conductor is "grounded," and with three-phase currents, if the neutral is "grounded" you surrender half your defenses. It only needs one fault upon some part of the system to give trouble. On the other hand, if the insulation of the two sides of a continuous-current service and of all parts of a three-phase service are maintained at a high figure, it needs at least two faults to cause a breakdown, and the chances of shock are very much reduced. The writer will conclude with the remark he made earlier in the article, that the whole crux of the problem lies in the two words: insulation and care.

The government commission that has been prospecting for coal in the vicinity of Concepcion and Talcahuano, Chile, has just published its report, which states there are more than 80,000,000 cubic meters of soft coal within an area of 80,000 square meters, or about 30.7 square miles. In places the vein is 3.5 meters, or about 11.5 feet, thick. The coal is said to be of fair quality.—*United States Consular Report.*

MODERN HOLMEN COALING STATIONS

*Written for Mines and Minerals, by Clyde P. Ross**

Editor's Note.—An examination of the diagrammatic elevation in Fig. 1 will convince engineers that it is a "motion study" applicable to mining, metallurgical, and other industries.

Methods of Handling Coal from Cars Into Bins for Coaling Locomotives

The editor's request for a detailed description of this coaling station from Roberts & Schaefer, who own the Holmen patents, was turned over to Mr. Ross, and the following article is his reply:

Appreciating that most railroad and engineering journals have from time to time published articles on handling coal for locomotives, and assuming that the reader is familiar with the reasons, the writer will particularize on what is known as the Holmen system of coaling locomotives, which is the original and most widely used in service.

Recently the United States Steel Corporation has had constructed at its round house at Waukegan, Ill., a fireproof structural steel coaling station, an elevation of which is shown in Fig. 1.

The station has a storage capacity of 100 tons of coal and 8 tons of dry sand, and is designed to coal and sand locomotives on two tracks. The coal is brought to the station on the receiving track at the rear of the plant in hopper-bottom cars and dumped into a 26-foot concrete receiving hopper. The rails of this receiving track are supported over the hopper on

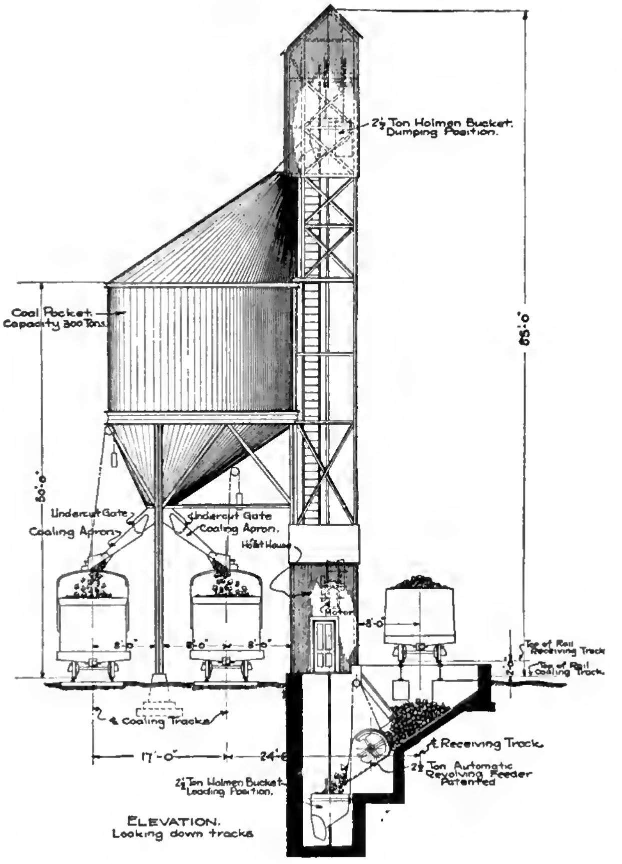

Fig. 1. Diagram of Holmen Coaling Station

24-inch 80-pound I-beam girders. The track hopper is lined with 1 inch of neat cement, sidewalk finish, with well-rounded valleys to the measuring feeder. This method of lining track hoppers has proven more satisfactory than wooden planks covered with steel, owing to the planks eventually rotting and the steel corroding.

* Contracting Engineer, Roberts & Schaefer Co., Chicago, Ill.

The coal from the receiving hopper flows by gravity into a Barrett revolving measuring feeder, which cuts out 1½ tons of coal and discharges it automatically into the elevating bucket, thus preventing overflowing the bucket and flooding the pit. This ingenious device is so designed that when in the act of discharging a measured quantity of coal into the elevating bucket, it closes up the opening in the track hopper as an undercut

Fig. 2. 300-Ton Coaling Station, Corning, N. Y.

gate. As the bucket is elevated, the feeder automatically rotates into its original position, opening the gate in the receiving hopper, and is then ready to receive another measure of coal. It remains in this position until the returning empty bucket descends and is again filled from the feeder.

The Waukegan plant is designed to elevate 40 tons of coal per hour with a single bucket balanced with counterweight. The bucket elevator is operated by a 15-horsepower, 220-volt, three-phase, 60-cycle, General Electric, alternating-current motor, equipped with solenoid brake, circuit breaker, special controller, with Hatch limit switch, a device to cut off the current and stop hoisting, provided the bucket is carried beyond the discharge point by a careless operator. This device makes the station "fool-proof." The motor is direct-connected to a reversible hoisting drum.

The round tank pocket which holds the coal is made of $\frac{5}{16}$-inch and ¼-inch steel plate, properly reinforced with a plate girder at the base to prevent distortion. The balance of the station is of structural steel, the columns being built-up angle and plate construction.

The hoist house and tower are covered with corrugated steel. The entire structure rests on concrete foundations and the bucket pit is waterproofed.

The coaling station at Corning, N. Y., shown in Fig. 2, is a good illustration of the use of reinforced concrete for structures of this kind. The foundation and entire superstructure is of concrete properly reinforced with steel, and is, therefore, of fireproof and permanent construction. The storage pockets are arranged to coal locomotives on two tracks beneath the pockets and on one track outside the pocket. The receiving track and receiving hopper are on the right side of the station in Fig. 2, enclosed with a concrete canopy roof to protect the men from the weather when unloading coal.

The storage capacity of the pocket is 300 tons of coal besides containing two dry-sand bins of 190 cubic feet each.

The receiving hopper is 40 feet long and is arranged to supply coal to two independent hoisting outfits, each consisting of a pair of Holmen balanced bucket elevators, together with a pair of automatic Barrett feeders. The hoisting capacity of each pair of elevator buckets is 125 tons per hour. The balanced buckets are connected by cable to the reversible hoists in the engine room and with the automatic revolving feeders

Fig. 3. 500-Ton Coaling Station, Delmar, Ind.

constitute practically an automatic hoisting apparatus. The driving power of each pair of buckets consists of a 20-horsepower motor. The coal is elevated about 55 feet above the railroad ties, automatically dumped, and lowered on curved chutes into the coal pockets.

The station illustrated in Fig. 3 is a 500-ton Holmen plant, built at Delmar, Ind., for the C. C. C. & St. L. Ry., by the Roberts & Shaefer Co., engineers and contractors, under the supervision of O. E. Selby, engineer of bridges and buildings of the railway company, at Cincinnati.

The station at Delmar consists of a frame superstructure with steel bin trusses supporting a 500-ton storage bin, which is elevated to a sufficient height to allow the coal to flow by gravity into the tenders, this being accomplished by the installation of standard undercut gates with hooded aprons over the two main line tracks.

At the right of the bucket tower or on the side of the structure is located a 36-foot concrete receiving hopper under the unloading track. The coal from the track hopper passes into two Barrett measuring feeders, which load two 1½-ton Holmen buckets. It is not necessary for the operator to watch the loading of the buckets, as this is accomplished mechanically. The increased efficiency of this measuring feeder is such as to bar from serious consideration a balanced bucket plant using the hand-operated slide gate. The two Holmen buckets are elevated alternately, that is, when one bucket is in the pit for the purpose of being filled, the other is at the top discharging its load of coal into the storage bin.

Each bucket is attached to a ⅞-inch crucible steel wire rope connected to a reversible steam hoist. The head-sheaves are of liberal size to insure long life and easy movement of the cable.

The buckets elevating the coal are opened at the top automatically at the proper elevation to deliver the coal to the pocket with a minimum amount of breakage and are also closed automatically after being emptied. As the bucket descends, it is immediately filled by the revolving feeder in the pit.

The operation of filling buckets, hoisting coal, and delivering it to the storage bin is under the control of one man, who merely operates the lever on the hoisting engine to put in operation the feeders and elevating machinery.

The average time required to fill and elevate a bucket of coal is usually about 1 minute and with two 2½-ton Holmen buckets an elevating capacity of 125 tons per hour can be readily attained. This machinery is also designed to elevate 40, 60, or 75 tons per hour, according to the requirements of the station, but the plant built at Delmar was designed with a 60-ton elevator.

Fig. 4 shows another coaling station recently constructed on line of the B. & O. R. R.

POWER GAS AND ITS DEVELOPMENT

The introduction of power gas has made considerable economy possible in the use of fuel resources. Blast-furnace and coke-oven gas, previously wasted, can be utilized and the replacement of steam power by gas power would diminish the annual consumption of coal for power by 9,000,000 tons, or 20 per cent., in England. Power gas can be generated from peat or other poor fuels not suitable for raising steam. There are 140,000,000 acres of peat bog in Europe. For small powers up to 30 horsepower, the use of coal gas is recommended rather than a gas plant; from 30 to 250 horsepower, a suction gas plant is recommended; and for greater power, a pressure gas plant. Recent developments are the use of the engine exhaust in place of steam in the producer, and the abolition of the gas holder in pressure gas plants, the production being controlled by fans driven by the engine.—*Chemical Trade Journal.*

POWDER-THAWING DEVICE

This is constructed by boring two 1½-inch holes in the side of a barrel, 6 inches from each end, in the same vertical line, fitting a 4- or 5-foot length of pipe into each of these holes and connecting the outer ends of the pipes with another length. A grating or rack is fixed in the barrel, on which a

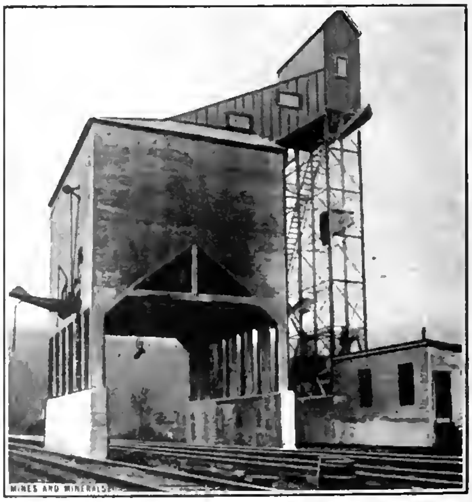

Fig. 4. Coaling Station on B. & O. R. R.

5-gallon oil can is placed containing the powder to be thawed. The open top of the can is just below the upper rim of the barrel. The barrel is filled with water to just above the upper pipe level and a fire lighted beneath the lower pipe near where the vertical riser connects it with the upper horizontal pipe, so that the heated water circulates. The powder in the can is said to thaw gradually and safely. The barrel and can are fitted with separate covers. The can should be cleaned after each operation, to remove any traces of exuded nitroglycerine. *Engineering Record.*

NOTES ON THE DELAGUA, COLO., EXPLOSION

Written for Mines and Minerals, by Geo. F. Duck, E. M.

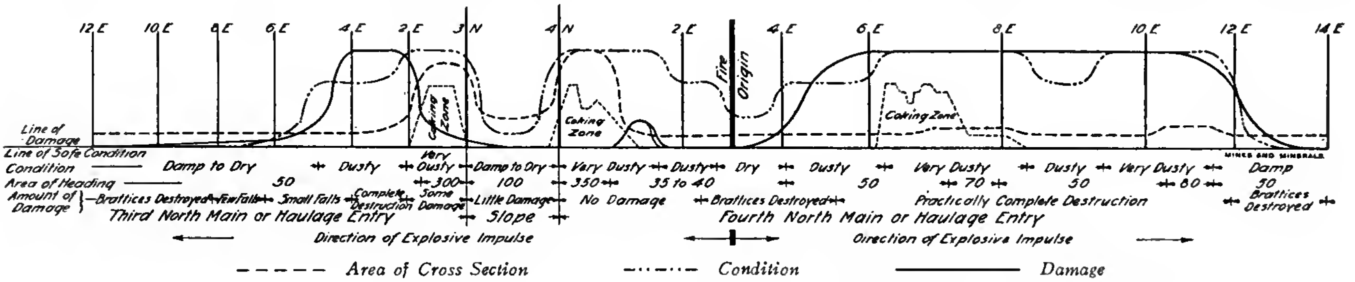
The Influence of Varying Areas and Conditions of Airways Upon the Propagation of Explosions

The explosion of the afternoon of November 8, 1910, in the No. 3 mine at Delagua, Colo., affords a striking illustration of the relation existing between the place and amount of damage done to the workings on the one hand and the condition and area of the entries concerned on the other.

In the general discussion of this accident in the January number of Mines and Minerals attention was called to the fact that the effects of the explosive wave were confined solely to the haulage roads and to but a portion of them. This limitation in the extent of the damage was due to two principal causes. One was the extremely wet condition of the entries as soon as a point was reached beyond which the abnormally dry entering air no longer absorbed the moisture artificially supplied to the mine. The explosive wave met a wet zone and stopped for want of fuel. The other, and fully as an important factor in limiting the spread of the explosion is found in that parallel entries were connected only at long intervals and not, as is usually the case, every few feet by connecting rooms driven in opposite directions. Each main heading and its cross-entries formed a panel in no way connected with the workings of an adjoining panel and an explosion originating in one block could not, as is often the case, be propagated through dusty rooms to an adjoining block. For these reasons the explosion was a simple one, and being simple, was easy to trace from its origin at the fire to the extreme limits of its spread, and this simplicity serves clearly to explain a few interesting facts concerned with dust explosions in general.

In tabulating some 300 or more observations made immediately after the accident, it became apparent, as stated at the outset, that at this mine, at least, there was a very clearly defined relationship existing between the size and dryness of the headings and the amount and location of the damage done thereto. An attempt has been made to show this relationship graphically in the accompanying drawing which is a longitudinal vertical section of the mine from the fourteenth east cross-entry off the fourth north main entry, outby the same to the main slope, up it to the third north main entry and in this to the twelfth east cross-entry. This covers all the mine where any damage was done except those portions of the main slope lying below the fourth north and above the third north main entries, respectively.

The figures and letters 14E, 12E, etc., refer to the fourteenth east, twelfth east, etc., cross-entries, and 4N and 3N indicate the place of intersection of the fourth north and third north main entries, respectively, with the main slope. The first line of the inscription below the drawing gives the condition of the roadways as observed 42 hours after the accident; the second line, the cross-section of the heading in square feet; the third line, the amount of damage done; the fourth line, the section of the mine concerned and the fifth line, the direction of the explosive wave from its point of origin at the fire.



Longitudinal Section of Delagua No. 3 Mine from 14th East Entry Off the Fourth North Entry Outby to Main Slope and Up Same to Third North Entry and Inby Same to 12th East Entry, Covering Section Damaged by Explosion

Area.—The line shown thus - - - - - indicates the change in area of the headings from point to point and is drawn to scale. It will be noted that the prevailing cross-section is about 50 square feet increasing to 70 and 80 feet at two points on the fourth north entry, at what are known as the seventh east and tenth east partings, respectively. At the intersection of the two main entries with the slope the area increased to 350 square feet at the fourth north and to 300 square feet at the third north entries owing to the network of sidings and to the fact that expansion was possible both up and down the slope.

Condition.—As stated in the January number the condition of the headings so far as dryness was concerned might be defined as very dusty, dusty, dry, damp, wet and watery in descending order from the most dangerous. It was also noted in the article mentioned that the road beds in any of the first three conditions could be classed as dangerous as the dust in them could readily be gathered up by the advancing wave and thus propagate an explosion. On the other hand a road bed in any of the last three states (from damp to watery) was essentially safe so far as furnishing dust for extending an explosion already started is concerned. If a dry condition be given a weight of one, a dusty condition a weight of two and a very dusty condition a weight of three, it is possible to draw what may be called a "condition curve" for the mine. This is shown by the line _.._.._... It is to be noted that all "safe" conditions, from damp to watery, are contained in the base line.

In justice to the Delagua mine it must be stated that the observations for condition were made from 42 to 72 hours after the accident during which time the entries had been subjected to an abnormally dry air-current. It seems probable, therefore, under usual working conditions that on the fourth north entry (for illustration) the improvement from very dusty at the slope to damp, that is to say, from highly dangerous to safe conditions, would have been reached within a much less space than was found to be the case such a length of time after the accident.

Damage.—The curve of damage or destruction as indicative of force, shown as a full line, is extremely difficult to determine, owing to the practical impossibility of finding a basis for comparison. Does it require more or less force to destroy a brattice than to knock down a set of timbers, to throw a small electric pump 3 feet than to shatter a pine door and scatter its fragments for nearly 200 feet along the entry? There appears no answer to these questions. On the fourth north entry inby the fire, the gradual increase in the amount of force as measured by the damage done could easily be traced, but outby the same it was more difficult. It was finally decided to consider the destruction as having reached a maximum when at least 90 per cent. of the timbers were destroyed and to grade the relative destruction from point to point accordingly.

Coke.—The zones of coking action are shown thus - - - - - and an attempt has been made to indicate the variation in amount of coking in each zone by fluctuations in the line deter-

mining it. One thing is apparent. Coking action is dependent solely upon the condition of the mine and is not affected by the area of the heading and bears no relation to the amount of damage done. On the fourth north entry coke was found at a place of maximum damage and also at the slope where the mine was practically unharmed. On the fourth north entry at the coking zone the area of the headings was normal, and at the slope the area of the zones was six or seven times as great as at the former place. In all cases coke was found where the mine was "very dusty," indicating that similar coking action might, if looked for, have been encountered at the tenth east entry on the fourth north entry.

The Explosive Wave Inby the Fire on the Fourth North Entry. An inspection of the drawing brings out the fact that the action of the explosive wave differed greatly inby and outby the fire and that this difference in action was due almost entirely to changes in the area of the cross-section of the workings. Inby the fire, except for a slight enlargement at the seventh east and tenth east partings, the headings maintained a practically uniform area of 50 square feet. Hence the "area curve" is essentially straight and parallel to the base line. The "condition curve," owing to the increasing dustiness of the workings, soon reached its maximum about the sixth east entry, which maximum was maintained with but one slight fall until near the twelfth east entry when, owing to the dampness of the workings, it took a sudden drop toward the base or line of "safe conditions." The "curve of damage" is also remarkably uniform. Starting from zero at the fire, this curve gradually reaches its maximum at about the sixth east entry, and maintains this until near the twelfth east entry when it also makes a sudden drop to the base, or line of no damage. It will be noted that in this portion of the affected area, the curves of condition and damage practically coincide.

The initial impulse to the explosive wave was probably given by the breaking down of the burning door, the jar consequent upon the sudden short-circuiting of the entire air-current throwing large volumes of finely divided dust into suspension. Ignited by the fire and drawn in by the momentum of the air, the dust began to distill gases until a point of explosive violence was reached at or about the sixth east entry. Owing to the dusty condition of the workings the explosion was propagated to nearly the twelfth east entry, when it stopped for want of fuel in the damp and wet headings. It is believed that, from the above, the following conclusion is warranted:

In straight headings of uniform area the violence of and consequent amount of damage done by a dust explosion is directly proportional to the condition of the workings.

The Explosive Wave Outby the Fire on the Fourth North Heading, the Main Slope and the Third North Heading.—It is apparent that the damage and condition curves for this portion of the workings are not related in the same manner as those in the section just considered. On the other hand if the first two named curves are studied conjointly with that representing the area, a relationship is at once apparent.

Starting at the fire as before, the explosive wave gained in force until at the "rock tunnel" it had sufficient energy to throw several mine cars full of rock and dirt into that heading. This is shown by the mound-like appearance of the curve of damage at a point about midway between the second east entry and the slope. Had the cross-section of the entry remained constant as it did inby the fire a point of maximum destruction would soon have been reached, and the curves of condition and of damage would have nearly coincided as before. But just after leaving the rock tunnel a network of sidings is encountered and soon thereafter a slope of large section, both up and down which the explosive wave had an opportunity to expand. At this point, then, the area of the workings suddenly increased from less than 50 square feet to 350 square feet or more, or in a ratio of not less than one to seven. Although the dust conditions were favorable to a most violent explosion and consequent great damage to the mine, this detonation either did not occur or had its force and effect practically nullified by reason of this opportunity for expansion.

Having split at the mouth of the fourth north entry a portion of the wave passed up the slope doing but very little damage in this enlarged and damp portion of the mine. At the mouth of the third north entry the wave again split, a portion continuing on up the slope to daylight and the remainder turning into the side entry. That portion passing into the third north entry gathered up a large amount of dust from the sidings and would have produced an explosion of extreme violence had it not been for the large area of the workings which permitted expansion in all directions. But just beyond these sidings there was a sudden contraction in area of from 300 square feet to 50 square feet or in the ratio of from six to one and the consequent concentration of force resulted in the total destruction of the entries at this point. Just beyond the fourth east entry the mine soon became dry, then damp, and the explosive wave was rapidly stopped, as on the fourth north entry, from lack of fuel.

The effect of a sudden change in area as influencing the amount of damage done by an explosive wave is also plainly brought out in that section of the slope just below the intersection of the fourth north entry. As stated before, a portion of the wave, which at the intersection of the slope and fourth north entry did no damage, went inward down the slope. Passing suddenly from a cross-section of 100 or more square feet to one of but 50 square feet, the concentration of force thus brought about wrecked the mine and was only stopped by a wet zone. It is believed that what has gone before warrants the conclusion that:

Under uniform mine conditions, whether of dryness or dampness, the force of and consequent amount of damage done by a dust explosion is inversely proportional to the area of the headings in the affected section of the mine. That is to say, when workings are uniformly dusty throughout, the damage done to the mine increases as the area of the heading decreases and vice versa.

Some other points affecting dust explosions were well exemplified by the Delagua accident, which in addition to the two named before may be summarized.

As it requires a certain length of time to heat dust to a point where gases begin to distill and during this interval the air-current is constantly in motion, the maximum force of a dust explosion is rarely displayed at its point of first origin.

Temperature alone is not a guide as to whether an entering air-current will or will not absorb moisture from the workings. The absolute amount of water in the air-current compared with that required to saturate it at the prevailing mine temperature is the only criterion. Consequently, while explosions of coal dust usually occur in winter because then the air for long periods is generally dryer than in summer, yet they may happen at any season of the year when (no increased watering being done underground) the air enters with a less total content of water than is demanded to saturate it at the mine temperature.

Explosions generally travel outby along the haulage road for two reasons. The haulage road is naturally more dusty than the return; and the amount and fineness of the dust, and hence the ease with which it can be thrown into the air-current, increase toward the intake. This increase in dustiness is due to the fact that the amount of coal hauled as well as the number of men and mules traveling per unit of distance increases as we approach the drift mouth, as well as to the further fact that the entering air is always dryest nearest the point of intake. There is thus a double reason for the amount and fineness of the dust increasing outby, and an explosion which feeds on dust must of necessity travel outby against the entering air-current for its food.

Coking action found is at or very near points of maximum dustiness, and its intensity does not necessarily indicate great explosive energy, merely great heat.

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

Hoisting Engineers' Examinations Held at Des Moines, Iowa, October 12

QUES. 2.—How much farther does the crankpin of an engine travel in one revolution (than the piston) when the length of stroke is 22 inches?

ANS.—The piston makes two strokes in one revolution and travels $2\times 22=44$ inches. The diameter of the crank-circle is equal to the length of the piston stroke, or 22 inches; and the circumference of this circle, or the distance the crankpin travels in one revolution is $3.1416\times 22=69.1152$ inches, which is $69.1152-44=25.1152$ inches farther than the travel of the piston in the same time.

QUES. 3.—Would you consider it best to suspend a boiler or to rest it on the walls that form the furnace?

ANS.—It is often preferable to suspend an ordinary flue or return tubular boiler rather than to allow it to rest on the furnace walls; because the walls are then relieved of the racking movement due to the alternate expansion and contraction of the boiler, which occurs to some extent even when cast-iron rollers are provided to allow for such movement. Also, there is less danger of the boiler being injured by unequal settlement of the walls.

QUES. 4.—When is a large boiler better than a small one?

ANS.—The size of a boiler is always to be determined by the work it has to perform, and due regard must be had for the future requirements. In the early development of a mine it is better to put in two or more boilers of sufficient capacity to meet every requirement for some time to come, and allow for the temporary cutting out of one of these for the purpose of repairing or cleaning. When the demand for power is variable it is better to use two or more small boilers than a single large boiler, so as to permit of cutting out some of them when the demand for steam is light.

QUES. 5.—In setting a hoisting engine where should the foundation be the heaviest? Where is the cast-iron bed of a hoisting engine most liable to crack?

ANS.—In mining practice employing a horizontal engine direct-connected or geared to a winding drum, the heaviest foundations are required under the winding drum, which must be securely anchored thereto by anchor bolts built into the foundation or made fast to anchor plates beneath the masonry. The cast-iron bed frame if improperly designed or if unequal settlement occurs may crack on the piston side of the pillow-block or journal of the crank-shaft.

QUES. 6.—Should the cogs of an engine seem to hammer what would be your conclusions?

ANS.—Hammering of the cogs of a second-motion or geared engine is often due to play between the gears, caused either by mismating, improper design, or undue wear of the cogs. It may also occur by reason of change of load or sudden application of the brake to the winding drum. A semifluid, tarry dope, manufactured specially for the purpose has been applied with good results to reduce the rattle of gears.

QUES. 7.—What size of cylinder would be required on a direct-connected hoisting engine capable of hoisting a load of 5,000 pounds from a depth of 300 feet in 11 seconds, allowing for acceleration and retardation in starting and stopping, respectively?

ANS.—Allowing, say 2 seconds for acceleration in starting and 2 seconds more for retardation in stopping, the maximum speed of hoisting would be the same as though the load were to be hoisted the entire distance in $11-\frac{1}{2}(2+2)=9$ seconds. The engine must therefore be capable of hoisting 5,000 pounds, including the weight of the rope, a distance of 300 feet, in 9 seconds, disregarding friction; or adding one-tenth to allow for friction, the load on the rope would be 5,500 pounds. This would require $\frac{5{,}500\times 300}{33{,}000}\times\frac{60}{9}=333+$ effective horsepower. Assuming an efficiency of about 85 per cent. in the engine, the indicated horsepower (I. H. P.) would be $333\div .85=$ say, 400 horsepower. Taking the mean effective pressure in the cylinder as 50 pounds per square inch, and assuming a piston speed of 600 feet per minute, the diameter of steam cylinder that would develop 400 indicated horsepower is

$$d=205\sqrt{\frac{400}{50\times 600}}=23.67, \text{ say } 24 \text{ in.}$$

If the engine makes 120 revolutions a minute the length of stroke is $(600\div 120)12\div 2=30$ inches; and the required size of the cylinder is therefore 24 in. $\times$ 30 in. under the assumed conditions. In hoisting practice it is customary to estimate on a duplex engine each cylinder of which is capable of developing the full power required.

QUES. 8.—In case of accident to one of a pair of engines at a critical moment, how would you proceed to cut out the crippled engine in order to use the other as a single engine?

ANS.—Shut off the steam from the disabled side by means of the stop valve. Then loosen the wedges behind the crankpin brasses and slide back the brasses so as to allow the connecting-rod to be removed from the crankpin and dropped to the floor. The valve rod need not be disconnected.

QUES. 9.—(*a*) Why are steam domes placed on boilers? (*b*) What purpose does the air chamber on a pump serve?

ANS.—(*a*) The chief purpose of the steam dome on a boiler is to obtain dryer steam in the engine by taking the steam from a point in the boiler high above the water where the water will not be entrapped by the steam as it flows into the steam pipe. The dome also increases the steam space of the boiler. (*b*) The air chamber on a pump serves to maintain a more uniformly constant flow of water, by means of the alternate compression and expansion of the air in the air chamber that takes place with each stroke of the pump. The compression of the air confined in the air chamber maintains a certain pressure between the successive strokes of the piston, which keeps the water moving, and avoids the great loss of energy that would otherwise occur from shock due to the water coming to rest between strokes.

QUES. 10.—(*a*) Explain the term suction. (*b*) What is the theoretical height of suction of water? (*c*) What is the height of suction practically?

ANS.—(*a*) Strictly speaking, there is no such thing as suction. The term is used, however, to describe what takes place when a vacuum is formed behind the piston of a pump. The pressure of the outside atmosphere acting on the water forces it into the vacuous space formed by the movement of the piston; and the pump is said to suck or draw the water. (*b*) The theoretical height to which water will thus rise into a perfect vacuum, or the theoretical suction, depends wholly upon the atmospheric pressure. This height in feet is equal to the pressure in pounds per square inch divided by .434; or multiply the height of the barometric reading in inches by the specific gravity of mercury (13.6), and divide the result by 12. Thus, at sea level the normal atmospheric pressure is 14.7 pounds per square foot, corresponding to about 30 inches barometric pressure. The theoretical height of suction, at sea level, is therefore $14.7\div .434=$ say, 34 feet; or $30\times 13.6\div 12=$ say, 34 feet. (*c*) The practical height of suction depends on the efficiency of the pump and pipe system. It may be taken in feet, ordinarily, as, at least, eight-tenths of the barometer reading in inches; thus, at sea level, $.8\times 30=24$ feet. It may be greater or less than this, depending on the pump.

QUES. 11.—How many volts and amperes of current would be required to burn five 108-volt, 2-ampere lamps, in series?

ANS.—When the lamps are connected in series a current of 2 amperes will be sufficient; but the voltage required will be $5\times 108=540$ volts.

QUES. 12.—How many volts and amperes of current will be required for five 108-volt, 2-ampere lamps connected in parallel?

ANS.—When these lamps are connected in parallel a current of $5\times2=10$ amperes will be necessary, while the voltage required is only the voltage of a single lamp, or 108 volts.

QUES. 13.—(*a*) Give the electrical unit of power. (*b*) Give its relation to the horsepower.

ANS.—(*a*) The watt is the electrical unit of power. (*b*) It requires 746 watts to equal 1 horsepower.

QUES. 14.—Find the indicated horsepower of an engine having a piston 12 inches in diameter and a stroke of 15 inches when the crank makes 140 revolutions per minute and the mean effective steam pressure is 50 pounds per square inch.

ANS.—$\text{I. H. P.}=\frac{50(.7854\times12^2)15\times2(140)}{33{,}000\times12}=\text{say, } 60 \text{ H. P.}$

QUES. 15.—Name some of the important parts of a hoisting engine.

ANS.—The important parts of the engine proper are the cylinder, piston and rod, cross-head, guides, connecting-rod, crank-shaft, crank-arm and crankpin, valve and valve rod, and eccentric. The answer to the question may also be made to include the winding drum, drum shaft of a geared engine, drum gear and pinions, drum brake, indicator, steam throttle and stop valves, lubricating cups, etc., etc.

QUES. 16.—For what use is a rope made of fine wires better adapted than one made of heavy wires?

ANS.—Lighter wires will stand less wear but are much more flexible than heavier wires. For this reason, ropes made of the lighter wires are better adapted to the purposes of hoisting, where the bending strains are heavy and the wear light; while those made of heavier wires are more often employed in haulage, where the bending strains are less and the wear of the rope greater. Where lighter wires are used a greater number of them are employed. Thus, for hoisting, six-strand, 19-wire ropes are quite generally employed; while six-strand, seven-wire ropes are more often used for haulage.

QUES. 17.—Explain the action of a sight-feed lubricator. Draw a sketch.

ANS.—A sight-feed lubricator is shown in section, in Fig. 1. The oil is contained in the large glass cup *L*, which is filled through the hole in the top, closed by the slide cover *A*. The needle valve *P* is raised or lowered by raising or lowering the cam-lever *C*, and the movement of the valve, which regulates the feed, is adjusted by the nut *D*, held in place by the lock-spring *E*. The glass cylinder *R* permits the oil to be seen as it drops through the small opening, shown as closed by the needle valve *P*. The cam-lever *C* is in its closed position; when this lever is thrown straight up the valve is open.

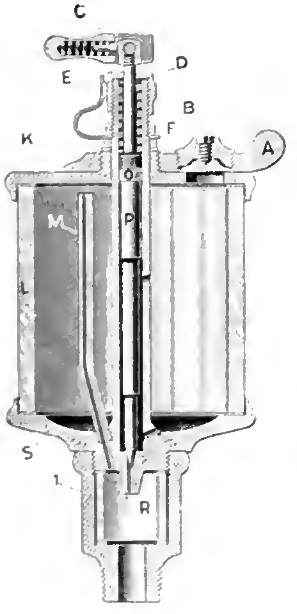


FIG. 1

QUES. 18.—What is the principle on which the injector depends?

ANS.—An injector is a device by means of which a jet of steam issuing from a nozzle, under high pressure, is brought into contact with water that enters a vacuum chamber, under atmospheric pressure. The steam imparts its velocity to the water by which at the same time it is condensed, forming a jet of water that forces open a check-valve by reason of its great momentum, and enters the boiler.

QUES. 19.—Explain the action of a pulsometer pump.

ANS.—This question is Ques. 18 of the mine foremen's examination and is fully answered as Ques. 26, page 541, MINES AND MINERALS, April, 1911.

QUES. 20.—What is the horsepower of a boiler 60 inches in diameter, 18 feet long, with fifty-seven 4-inch flues?

ANS.—The circumference of a 4-inch flue is $3.1416\times4=12.5664$ inches. Multiplying this by 57, the number of flues, and adding to that result the semicircumference of the boiler in inches (assuming one-half of the boiler shell is exposed to the flame); then dividing by 12 and multiplying the last result by the length of the boiler in feet, gives

$$\frac{57\times12.5664+3.1416\times60}{12}\times18=1{,}357 \text{ sq. ft.}$$

To this must be added, say one-half the two end areas of the boiler, less $2\times57=114$ times the sectional area of a 4-inch flue. Thus, $.7854\times60^2-114\ (.7854\times4^2)=.7854\times1776=$ say, 1,395 square inches, or 9.68 square feet. The total heating surface is therefore, say, 1,367 square feet. For a horizontal tubular boiler the rated horsepower is estimated from its heating surface as varying from 14 to 18 square feet of heating surface per horsepower. Taking the average rating of 16 square feet per horsepower, the power of this boiler is $1{,}367\div16=85$ H. P.

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the COMMISSIONER OF PATENTS, WASHINGTON, D. C., at the following rates.

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
An entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED MARCH 7 TO MARCH 28, 1911, INCLUSIVE

No. 985,909. Coking and gas-generating oven, Heinrich Koppers, Essen-on-the-Ruhr, Germany.

No. 986,389 Concentrating device for mineral ores, Herbert T. Herr, Denver, Colo.

No. 986,271. Process of refining and agglomerating ores and the like, Hugo Dicke, Frankfort-on-the-Main, Germany.

No. 986,813. Ore-cooling apparatus, James Belcher Etherington, Winthrop, Mass.

No. 986,608. Roller ore-crusher, Lamartine C. Trent, Reno, Nev.

No. 986,709. Furnace for roasting ores, Nicholas L. Heinze, La Salle, Ill.

No. 987,642. Coal-washing jigger, Thomas H. O'Brien, Dawson, N. Mex.

No. 987,179. Jigger, Wilhelm Seltner, Schlan, Austria-Hungary.

No. 987,209. Ore-concentrator, Henry E. Wood, Denver, Colo.

No. 987,428. Apparatus for the treatment of ores and for the electrolytic deposition of gold and silver and other metals from solutions containing said metals, Frederick Capel Brown, Komata, New Zealand.

No. 987,156. Treatment of sulphide ores, James A. McLarty, Toronto, Ontario, Can.

No. 987,941. Coke oven, Louis Bansart, Johmont, near Haine, St. Pierre, Belgium.

No. 987,993. Coke oven, William J. Kearns, Dunbar Township, Fayette County, Pa.

No. 988,029. Hammer drill, William Prellwitz, Easton, Pa.

No. 987,744. Miner's lamp, Paul Rennert, Hagen, Germany.

No. 987,866. Ore concentrator, Henry Earle, Denver, Colo.

No. 987,850. Process of treating ores, Isaac A. Braddock, Haddonfield, N. J.

No. 987,832. Pipe Fishing Tool, E. Seibert, Didsbury, Alberta, Canada.

No. 988,293. Pulverizing Mill, J. R. Moffitt, Denver, Colo.

No. 988,230. Producing synthetic sapphires, A. V. L. Verneuil, Paris, France, Assignor to L. Heller & Son, New York, N. Y.

No. 988,255. Screening and Picking Apparatus, Joseph Dodds, Rutherglen, Glasgow, Scotland.

Mines and Minerals

Vol. XXXI—No. 11. SCRANTON, PA.—JUNE, 1911—DENVER, COLO. Price, 25 Cents

BUFFALO-SUSQUEHANNA SAGAMORE MINE

*Written for Mines and Minerals, by R. Dawson Norris Hall**

Surface Plant at a Modern Bituminous Coal Mine, Capacity of Tipple 1000 Tons an Hour

The Sagamore mine, operated by the Buffalo and Susquehanna Coal and Coke Co., lies as shown in Fig. 2, on both sides of the line dividing Indiana and Armstrong counties, Pa., most of the acreage, the town and plant being on the Armstrong County side of that line. The mine is reached by the main line of the B. & S. R. R., that railroad being broken by a gap between Sykes and Juneau, which is temporarily filled by the use of the Buffalo, Rochester & Pittsburg Railroad between these points. The portion of the B. & S. R. R., between Juneau and Sagamore, proceeds by Canoe Creek, Little Mahoning, and Plum Creek, a distance of 21 miles, cutting off a triangular strip of Indiana County in its northwest angle.

The only available way of reaching the coal by drifting exhibited itself on Little Plum Creek, the coal around the tipple running everywhere in an unbroken field from the center of operation. It was possible therefore and advisable to erect at this point a large plant capable of handling the entire field, for at no other point was it convenient of access.

The method so often advocated, and with so much justice, of small scattered units of lower capacity served by a central power plant and so arranged as to avoid the congestion too often found in a larger plant, did suggest itself to the management. But as the crop on Plum Creek extends barely 9,000 feet, there seemed inadequate room for two complete tipple outfits with all the trackage now found so necessary, above and below the tipple. It was therefore decided to build the two tipples proposed into one structure, side by side. The coal also crops in Big Plum Creek, but though drainage at this point was a trifle more convenient for a portion of the territory, here the plant would have been at the very confines of the field, increase of tonnage would have been slower and long haulages would have resulted with accompanying additional equipment. Moreover an economy in railroad construction was effected, for otherwise an extension of the road to Big Plum Creek would have been necessary. Every care has been taken to avoid congestion by having adequate accommodation and provision for a large capacity. The usual problem presented is between several plants or only one along a river front, or between many shafts or a single shaft sunk to a completely buried seam; and in these cases a number of small plants is preferable to one big one. But all through central and northwestern Indiana County, it is possible to avoid the expense and inconvenience of sinking and working shafts by concentrating at favorable points in the field, and the result is that this section has been exploited in no other manner. Sagamore is only one of many large plants in this section; small operations being seldom found.

The area comprises roughly 10,000 acres of excellent coal. The bed mined is the Upper Freeport and has an average thickness of 4½ feet.

The preparation of an agricultural region, several miles from any railroad, for the operation of mines in their preliminary stage, prior to the arrival of the projected means of transportation, involves the construction of many temporary structures and installations. Almost every large mine has to be so constructed today that the railroad built to remove its coal may earn a dividend as soon as the track is completely laid. Moreover a modern mine requires too lengthy development to admit of the inception of its operations being delayed.

To this end, Sagamore was provided with two portable sawmills and four temporary power houses, each of the latter accommodating two mines and each equipped with two boilers of locomotive type of 50 horsepower each, and one Sullivan air compressor. These compressors were afterwards distributed at other plants of the same company. A large amount of stock coal accumulated between March 22, 1905, the day when ground was broken, and November 29 of the same year, when part of the stock was loaded into cars from a temporary tipple.

Little Plum Creek, having a grade of 26 feet to the mile, like all streams on a gentle grade, meandered freely from side to side of the valley and for half a mile this troublesome stream was provided with a new and more efficient channel to permit

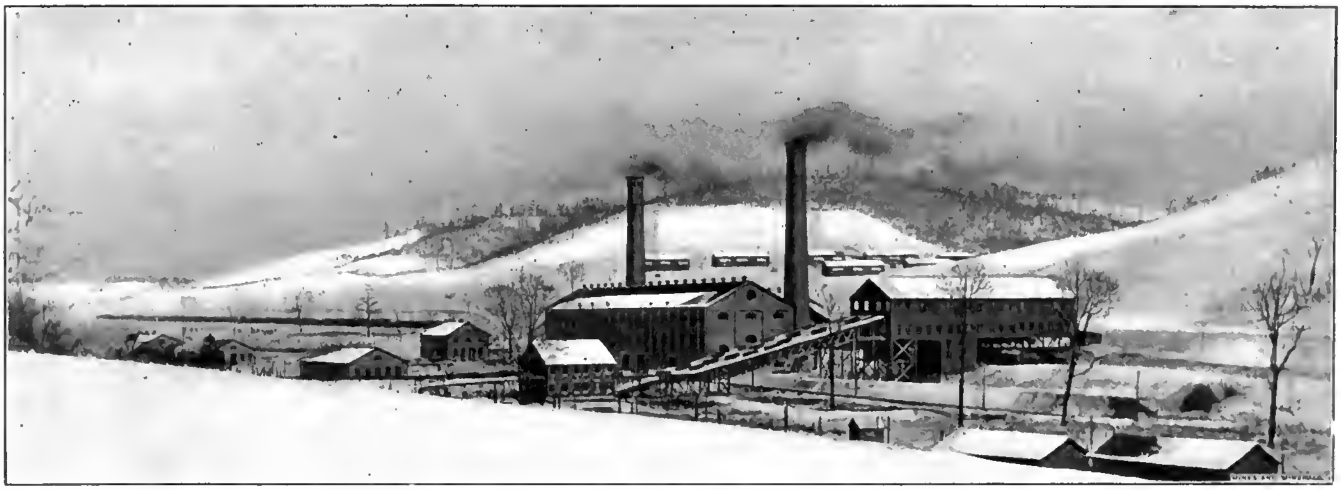

Fig. 1. Sagamore Plant, Buffalo and Susquehanna Coal and Coke Co.

*Mining Engineer, DuBois, Pa

of the erection of permanent buildings and railroad tracks in and around the ground formerly made useless by its irksome ubiquity.

Above the projected power house, a dam confined its waters for use in the boilers, but now the water from what were Artesian wells, but which now require to be pumped, is used in preference to the creek water.

There is nothing much demanding consideration in the underground projection of the Sagamore mines because the roof breaks freely and the cover is not heavy, so no elaborate or expensive treatment of the roof problems was necessary. The roof is generally of sandstone but occasionally slate appears. The bottom is of fireclay. There has never been the slightest premonition of any squeeze or creep. The room and pillar advancing method is everywhere followed. The rooms are made 24 feet wide, the pillars 16, and are, when conditions permit, 300 feet long. All chain pillars in both butt and face headings are 48 feet thick, while the wing pillars flanking the face headings on either side are kept 100 feet wide. The headings are driven 12 feet wide and occasionally the rock from these is loaded into gobbing holes instead of being brought out for disposal. The fact that the operation consists of eight separate mines with wide headings ventilated by eight distinct fans, makes it necessary to provide only a few headings in parallel system to furnish sufficient ventilation for each unit. The three-heading system is that commonly adopted, but four headings in parallel are sometimes used. Despite this fact, a sufficient current of air is furnished with a low velocity of air-current. The fans are all 10'×4' Clifford-Capell, non-reversible blowing fans, belt driven by 100-horsepower motors capable of producing 100,000 cubic feet of air per minute against a 4-inch water gauge.

All the coal is mined by machines; there is no hand-pick work. Some of the men both cut and load their own coal, and it is this fact which reduces the output per machine, which would be very much greater if steady cutting were provided for each machine. There are 72 Sullivan machines and these cut not only the rooms and headings but also all the pillars in the mines.

The track gauge is 3½ feet, and mine cars have a capacity of 2 tons. The cars are hauled by 6 Jeffrey and 6 General Electric locomotives ranging in weight from 12 to 14 tons, and each capable of pulling 100-car trains.

The floor of the mine rolls in gentle undulations, but as an anticlinal makes its appearance at the railroad, there is on the whole an uphill grade against the loads throughout the mine which does not average over 1 per cent. The tipple, shown in Fig. 1, is a large steel structure of the car-haul type, that if run at full capacity is amply competent to handle 1,000 tons per hour, although at present the tonnage does not exceed 4,000 tons per day. The cars are brought up the incline by a moving chain, one by one in a steady stream, weighed and dumped. They then pass on over the dump and reach a kick-back, returning thence to a retarder which lowers them to the empty track. This is elevated above the loaded track, by which the cars approached the tipple, so that the grade favors the haulage plant, both approaching and leaving the foot of the hoisting incline. To handle so large a tonnage as is contemplated, three Phillips cross-over dumps are installed.

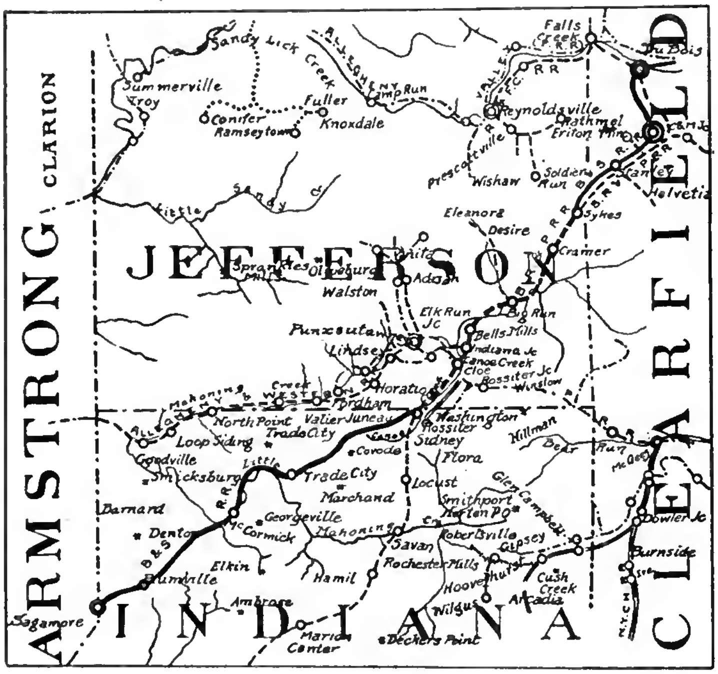

Fig. 2. Map Showing Location of Sagamore

Under the tipple, Fig. 3, are four tracks with two miles of aggregate storage for cars both above and below the dump. A "scissors" cross-over, Fig. 4 (*a*), connects all the empty tracks together conveniently near the tipple so that any car can be shifted to any track with ease and dispatch. This could have been arranged by the construction of a "double ladder" as shown in Fig. 4 (*b*), but there are objections to such an arrangement, as it takes up so much more room, since only one track can be made really straight and therefore all cars but those on that track must round the curves which constitute the ladder and because, with it, the cars have to be kept so far from the tipple The plan which involves the "scissors" cross-over is the only one which provides for placing cars on whatever track is desired without unnecessary congestion, and loss of room, together with minimum resistance to the motion of the cars and minimum risk of derailment. But above all, this method of arrangement saves many unnecessary steps to the car dropper.

The grade on the railroad loading tracks is 2 per cent. for 50 feet above and below the tipple. At this point each car in its transit has to be handled separately and must be stopped and started several times. But with such an abundance of grade there is no danger of the output of the mine being suspended by the stalling of a stiff car. Below the tipple, the grades run from 1½ per cent. down to 1¼ per cent., but above, where empty cars have to be handled, the grade is 1.6 per cent.

To avoid breakage of coal, the tipple was provided from the first with shaking chutes. This reduced both the height of the structure and the destructive momentum due to the well-known impossibility of regulating the fall so as to suit coal of every size and shape, subject to differing frictional retardations due to its location in the pans and to changes of temperature and weather.

A new method of saving coal from disintegration whilst being loaded is being installed at the tipple in accordance with the designs prepared in the office of the chief engineer. The purpose is to forward and lower the pan when the coal is low in the car and draw it back and raise it when the section of the car being filled is nearly full. The pan dumps lengthwise of the tracks. A basket could be used to lower the coal but that device has to be lowered and raised for every mine car unloaded. On the other hand this pan permits a continuous flow of coal even when the elevation and position of the point of delivery is being adjusted.

The first idea was to regulate the point of discharge by a simple elevation of the end of the pan to permit of the passage of the highest steel gondolas under it. But such a pan creates difficulty inasmuch as raising one end of the pan and leaving the other stationary causes the slope of the chute to be so reduced that the coal will cease to flow. It was accordingly

decided to design a pan which could be raised at the will of the car trimmer and which nevertheless would retain the same or approximately the same pitch. This was accomplished by providing a track on which the pan could travel and installing a long air cylinder operated by compressed air to furnish the power to move the pan back and forth whilst the end was supported by a hanger of unvarying length.

The power house is a massive piece of construction as the illustration shows; the engine and boiler rooms are set parallel

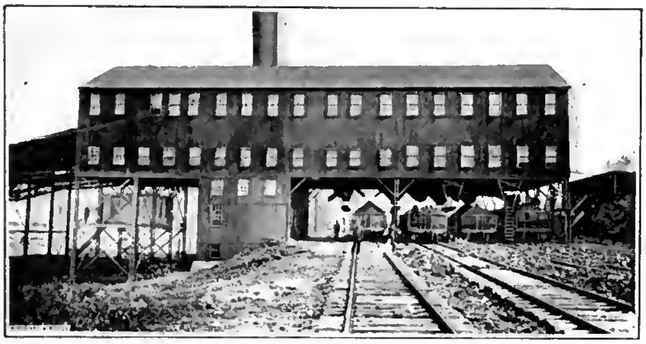

FIG. 3. LOADING TRACKS AND TIPPLE, SAGAMORE

to each other but side by side, separated for cleanliness and fire isolation by a party wall 36 feet high, the full height of the building. The power house is provided throughout with a concrete floor reinforced with iron, the lower part or basement being used for the piping and for the delivery of ashes from the boilers. The roof is supported by steel trusses and covered with slate. The engine room measures inside 67 ft. × 324 ft., and the boiler room 39 ft. × 260 ft. In the latter, as shown in Fig. 5, are five batteries of Rust vertical water-tube boilers of 350 horsepower each, making 3,500 horsepower in all. These are fired by Murphy automatic stokers. The fuel is supplied by a belt conveyer from the tipple; this runs from a bin under the screen to an overhead storage bin and the coal is distributed by a traveling automatic tripper. One man tends to the fires, dumping the ashes into hoppers beneath the furnaces whilst another man takes care of the water supply of the boilers. These two men do all the work of the steam raising. Judging by other plants, at least 8 men are saved by the use of automatic stokers, which is a considerable saving when the cost of a year's stoking is considered. This saving would not be so apparent were the plant of less capacity and it must also be remembered that by using this automatic feed, the boilers can be made to give satisfaction using the finest and most unmerchantable slack.

The ashes from the boilers, dropped into concrete hoppers, are sprinkled with water and hauled away from the basement in special ash cars by an electric locomotive and dumped from a staging into railroad hopper cars. To effect this, a special form of dump has been provided. The trestle will hold several ash cars, and as many as desired are pushed by the motor up an easy incline to the top of the trestle. They are permitted one by one to drop back to the head of the incline. There, singly, they are stopped on a revolving dumping table, turned a quarter circle and dumped into a railroad gondola or hopper standing below. The tilting of the dump is performed by a small cylinder pivoted at the lower end. Thus speedily and cheaply the ashes are removed from the plant and delivered to a place where they can be made to fill a useful purpose.

The water for the boilers is supplied from six wells and is pumped into two Stillwell feedwater heaters. Like all boiler rooms with automatic stokers, it is cleanly in the extreme and it is possible to keep the engine room in perfect condition despite the fact that the two are ranged side by side. The power house is flanked at each end by a brick stack 150 feet high, lined with firebrick and of 12-foot inside diameter, supported on concrete foundations. An arched concrete underground flue connects the boilers with the stacks.

In the engine room are three C. & G. Cooper cross-compound engines with 20- and 34-inch cylinders and 42-inch stroke, making 100 revolutions per minute, directly connected to Crocker-Wheeler dynamos of 500 kilowatt capacity generating a direct current of 500 volts. The Ridgway Dynamo and Engine Co. supplied the dynamo for furnishing light. It has a capacity of 100 kilowatts and furnishes an alternating current of 1,100 volts, being a 60-cycle generator coupled directly to a McEwen engine.

There are also four Allis-Chalmers cross-compound air compressors. The high-pressure steam cylinders have a diameter of 26 inches, the air cylinders are of 26-inch and 44-inch diameter, respectively, and the stroke is 48 inches. Each compressor produces 5,000 cubic feet of air per minute at a pressure of 100 pounds to the square inch with the horsepower rating of 1,000.

Along the full length of the engine room and hung 26 feet above the floor, travels a standard erecting and dismantling electric crane of 22 tons capacity, manufactured by the Northern Engineering Co.

A standard gauge railroad track, connected with the B. & S. R. R., enters one end of the engine room, and space is provided for one car to stand inside the power house for convenience in loading any injured machinery or for unloading any additions to the equipment.

All piping in the engine room is beneath the concrete floor. The pipes from the header over the boilers drop through the floor and are passed through the concrete wall of the engine room basement, holes being provided large enough to permit of all possible side motion resulting from changes of temperature in the steam lines. This provision keeps the engine room clear, with the head room entirely unobstructed. In both sides of the power house, there is abundance of room. On the boiler side, there is accommodation for four more batteries of boilers, and on the engine side for another large compressor and two generators, the size of those already installed.

Four receivers stationed outside the power house receive the air from the four compressors. Air leaves these at 80 pounds per square inch pressure and is conveyed by pipe 14 inches in diameter, branching eastward and westward toward the mines. This dimension is reduced at each mine opening, the pipes off-bearing to the drifts being uniformly 8 inches in diameter.

The locomotive barn, car-repair shop, and machine shops, are all one story brick buildings, 13 feet high with frame roof trusses, covered with slate, and foundations of concrete. The first measures 40 ft. × 102 ft., and the other two 40 ft. × 100 ft.

The locomotive barn has in front one pair of double-swinging doors for each track, separated by door posts only.

There is room for 24 motors though only 12 are now in use. Twelve separate tracks with 7-foot centers enter the building

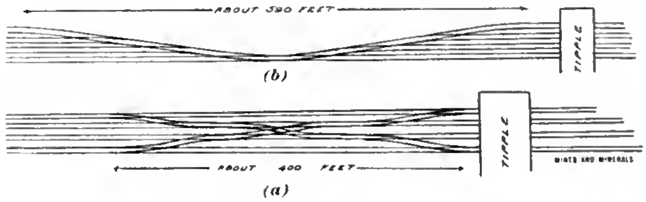

FIG. 4. "SCISSORS" AND DOUBLE-LADDER CROSS-OVERS

and these being of 80-pound rails need only occasional support, which is afforded by 12″ × 12″ brick piers set 8 feet apart and rising 4 feet above the basement floor on which they stand. The tracks are open and the space between the tracks floored, as shown in Fig. 6. The building is heated by steam and lighted by electricity.

The importance of an adequate and well-heated locomotive barn is considerable. In the first place it provides a place for

a close inspection of the locomotive after the day's work is done. Resting as the locomotives do in this Sagamore barn on heavy rails supported by pillars, not by walls, it is possible to travel all around, under as well as over them, tightening loose bolts and making complete inspection. For this inspection portable lights having long leading wires are provided. A locomotive should not be permitted to become unduly chilled for when it enters the saturated air of a drift mine, it immediately becomes

Fig. 5. Boiler Plant, Sagamore

covered with condensed moisture with bad results. The difficulties encountered by the electrical firms in providing adequate insulation have been not a little increased by a lack of consideration on the part of the mine owners as to the need to such machinery.

Fourteen feet of the east end of the barn is partitioned off and used as a repair shop. An 8-inch I beam running lengthwise of this shop carries a small traveling chain hoist for use in dismantling locomotives. A concreted pit under the track serves to remove worn wheels from the locomotive and to provide for the emplacement of new wheels. For this purpose the locomotive is jacked up, the rails over the pit removed, the axle and wheels lowered to a small truck beneath and hauled outside.

The car-repair shop has two mine tracks running lengthwise of the building. In addition to the usual power grindstone and emery wheel, an automatic cut-off track saw and a large drop hammer are installed. These tools are all operated by an electric motor. Special attention may be drawn to the fact that the hammer, in addition to its most usual uses, shapes all the machine picks used at this plant. By the use of special dies, bar steel is hammered out in the rough, a very little hand-shaping followed by tempering resulting in a finished pick. All the general blacksmithing is done in this building, and five concrete forges are provided. One large forge in the center of the building is used whenever a large open space around the fire is desirable. The other four are set near the walls and these are in continuous use. The floor of this shop is of cinders and the lighting is by electricity.

The machine shop has a concrete floor with $2'' \times 4''$ sills laid flush with the top and over these are nailed $\frac{7}{8}$-inch tongued and grooved yellow pine flooring. The mine track enters one end and runs through the building. The equipment consists of an 8-inch pipe machine, a large drill press, a planer and a shaper, all operated by an electric motor.

The supply house is most elaborate. Supplies are not allowed to go to waste or to be lost sight of, so as to be unavailable when required, nor is there any looseness and uncertainty as to the necessary provision in case of a breakdown. Where no storehouse control is maintained there is always a large loss in keeping small duplicate parts on hand. The need for them is felt only at long intervals, and when it appears the personnel may be changed, the duplicates may be covered up or may have been used in some other place or even with careless management destroyed. So that not only is the delay sustained, but good material, purchased for the occasion, is made unavailable or valueless. All the bins, shelves and racks are carefully stenciled with the size and nature of their contents. The storekeeper not only keeps a vermin and dirt-proof depository, but also an account of material by an accurate card system which records the nature of distribution and the stock on hand. A two-story brick building measuring 100 ft. $\times$ 40 ft. $\times$ 30 ft. houses the supplies. The first floor contains racks and bins, in the center of the building and along the walls, for all the heavier mine supplies. On this floor, the storekeeper has his office and shelves are provided for lighter parts. A mine track, extending 20 feet into the building, provides for the transfer of heavy material.

The bar iron is stored on a large vertical rack within the building. The lower floor is of concrete. A hand-power elevator of half a ton capacity connects the floors. The second floor is arranged with bins and racks mainly for supplies of lighter weight, but the bar iron rack extends through to this upper story. The railroad supply track passes the unloading platform on a level with this floor. Here also electric lights and steam heat are provided. The oil is kept in a separate brick building on the opposite side of the supply track.

The town is laid out in separate sections called wards, on ground sloping in all directions separated by small streams affording good drainage and isolation in case of serious fire. The streets are 40 feet wide and fronts of houses 20 feet back of street line. The building lots are 50 ft. $\times$ 130 ft. with a rear alley 12 feet wide.

The houses are in four styles, built on hollow block tile foundations, studded and covered with double half **V** and siding, underlaid with heavy building paper then lathed and plastered and roofed with slate. The water supply is from three Artesian wells near the creek and pumped through a 6-inch cast-iron pipe to a double concrete reservoir holding 80,000 gallons on

Fig. 6. Locomotive Barn, Sagamore

each side, located at the highest point in the town. This 6-inch pipe serves as a main for the town system with 4-inch cast-iron lines leading from it through each street, set $3\frac{1}{2}$ feet underground. Thus the piping system can be supplied direct from the pumps or by gravity from the reservoir. From the 4-inch lines $\frac{3}{4}$-inch branches are laid to domestic hydrants at the sidewalk, spaced 100 feet apart, and located on alternate sides of the street. At all street intersections and along the streets at

intervals not exceeding 400 feet fire hydrants are placed. The elevation of the reservoir is higher than the highest house. Each ward has an organized fire brigade and is provided with a hose house containing a hose cart and 150 feet of hose.

The public school, located in a natural grove, is large and modern in every respect, containing four class rooms upstairs and four downstairs, all 24 ft. × 30 ft. 6 in. with a cloak room adjoining each class room. A drinking fountain is provided at each floor, and toilet rooms are found in the basement. The building is of brick cased, built on stone foundations. It is roofed with slate and heated by steam. There is a hotel with 31 bedrooms, in keeping with other improvements, a fine brick office (with two office rooms, a drafting room and three bedrooms and a two-story vault) and other conveniences are all interesting parts of this equipment.

Nor in these days, when the care of the injured is a paramount consideration, should reference be omitted to the doctors' office arranged with a waiting room and two offices, one for each physician. There is provided also an operating room with a concrete floor, a central drain for efficient cleansing of the room, every facility for cleanly operating, and a sterilizing cabinet. This departure may be described as a connecting link between first aid and the hospital. Here minor injuries can be adequately handled and professional aid in the case of major injuries can be supplied before the long distressing trip to the distant hospital commences. Sagamore, it must be remembered, is on a different railroad, and 30 miles from the nearest hospital; viz., that founded by Mrs. Adrian Iselin, at Punxsutawney.

The store of the Keystone Store Co. is a large two-story building, measuring 66 ft. × 110 ft.

The main details of this comprehensive plant were laid out under the immediate direction of Chas. D. Oldknow and Jas. Harvey. The former is chief engineer, whose previous affiliation was with the Temple Iron Co., of Scranton. The latter, who has made mining a life study, is the very capable general superintendent. H. A. Molder is the directing head at Sagamore, and J. A. Caseley is the auditor. The steel work and trusses and the mechanical equipment of the tipple and power house were detailed and constructed by the contracting engineers, Heyl and Patterson, of Pittsburg.

COAL NOTES

Steel vs. Wooden Cars.—An English engineer, basing his opinion upon experience, says: "In coal seams lying horizontally, or only slightly inclined, steel mine cars are best, and last a long time without any considerable cost for repairs; however, where the coal seam is inclined, wood cars are preferable, by reason of their necessary frequent renewals or repairs caused by the breakages general in these seams."

British Columbia Labor Troubles.—At this writing the labor troubles in the Northwest are unsettled and operators are preparing for a period of idleness. The railroads are contracting for coal in the United States. Large shipments will be made over the Great Lakes into Canada. The Great Northern is seeking to place contracts for coal in the states of the Northwest. Under these circumstances it will not be long before the operators and miners settle their differences by arbitration.

New Washington Mine Commission.—An act was recently passed creating a commission to investigate the operation of coal mines in the state of Washington; to revise the coal-mining laws of the state and to report their conclusions to the next legislature. Washington has had but one mine inspector, but the last legislature authorized an assistant inspector to be appointed by the governor.

Coal Beds Under Scranton.—In all there are 11 coal beds under Scranton, known by names as follows, beginning with the highest:

No. 1. The 8-foot coal bed. It only exists in two small areas or islands under the highest part of Hyde Park hill. No. 2, 5-foot bed; No. 3, 4-foot bed. These are in the hill top on the West Side only, from Dodge mine to Marvin mine above the level of the Lackawanna River. No. 4, the Diamond bed, No. 5, the Rock bed. These are on the West Side of the Lackawanna River only, under Bellevue, Hyde Park, Providence, and, parts of Keyser Valley. No. 6, the Big or 14-foot bed, No. 7 New County seam. These extend under the whole West Side and also become the surface vein on the East Side at the National Colliery near the south line of the city, also in the central city and hill section nearly to the Moses Taylor hospital. No. 8, Clark bed, No. 9, Dunmore No. 1, No. 10, Dunmore No. 2, No. 11, Dunmore No. 3. The latter four beds are under the whole city from Nay Aug Park to West Mountain.

The average thickness of the 8-foot bed is 7.6 feet; of the 5-foot bed 4.4 feet; of the 4-foot bed 3.6 feet; of the Diamond bed 9.4 feet; of the Rock bed 5.2 feet; of the Big bed 12.2 feet; of the New County seams 6 feet; of the Clark bed 6.7 feet; of Dunmore No. 1, 3 feet; Dunmore No. 2, 4 feet; and of Dunmore No. 3, 3.3 feet. The lower Dunmore at Price-Pancoast, called No. 4 or China bed.

Coke Ovens in Great Britain.—The *Iron and Coal Trades Review*, of London, states that at the close of 1909 the number of beehive coke ovens in Great Britain, was in England 16,346, in Wales 173, and in Scotland 874, making a total of 17,393. As there were at the time 6,789 retort ovens in use, the entire number of ovens of all classes was 24,182.

Natural Gas Supply of Ontario.—The county of Welland and adjoining county of Halimand furnish most of the natural gas in Ontario. There are about 500 producing wells, some of which furnish 1,500,000 cubic feet daily. The depth of the wells ranges from 550 to 3,000 feet. Prices for gas are 15 to 45 cents per 1,000 feet, according to quantity used. Gas is piped to Hamilton, Niagara Falls, Ontario, and as far west as Brantford and Paris. Farmers and country villages are supplied at retail prices, while iron works, smelting works, and other manufactories in Welland are supplied at wholesale rates. It is estimated that over 30,000,000 feet are produced daily in this district.

India's Coal Output.—According to the principal address delivered before the Mining and Geological Society of India with reference to the coal industry it was said that after the serious setback of the last two years there seems every prospect of better times. In 1909, 2,544,610 tons of coal were exported, while during 1910 the shipments rose to 3,167,481 tons. This is the highest figure yet attained, being higher even than that of 1908, when 3,095,748 tons were shipped. Regarding the quality of Indian coal, it is alleged that the fuel from the best seams compares favorably with that produced in Japan, Australia, or South Africa, which are the keenest competitors; and with low costs of production Indian coal should be able to hold its own in the eastern market.

Moistening the Air.—President Kuhn, of the Pittsburg-Westmoreland Coal Co., has devised a simple method for lessening the dangers of explosions, particularly dust explosions, on cold winter days, when the danger from this source is greatest. When the temperature is low the moisture in a mine is quickly absorbed by the ventilating current on account of the dryness of the air, and to overcome this feature Mr. Kuhn has exhaust steam turned into the fan houses at all his mines following a sudden drop of temperature. This keeps the air-currents moist and prevents the mines from becoming filled with dry dust. Other companies in Western Pennsylvania have adopted the plan of late and many mining men are of the opinion that it minimizes the danger of dust explosions.

Erasmus Haworth, State Geologist of Kansas, has issued a special warning to all coal operators and miners in which he says: "Do not presume your mine does not make gas, all coal mines do." An abstract of his "warning" which appears on another page, will be found interesting reading.

THE CARE OF MINE MULES*

Written for Mines and Minerals

Importance of Care in Choosing Animals for Underground Work and of Proper Treatment and Feed

Outside, away from the immediate vicinity of a coal mine, did you ever see a dead mule? No less an authority than Frank Amos, of the Fairmont Coal Co., made the statement "that the average life of a mine mule was 3½ years, and unless conditions were changed to prolong life, the use at the present cost of the animal was unprofitable."

When an animal of this kind lives indefinitely on the farm it seems incredible that his life should be shortened to 3½ years in the mine. There are mules today in anthracite mines that have been working 20 years, yet it is probable that the average life of such animals in all anthracite mines does not exceed 5 years. Most mules come to an untimely end through accidents; however, a large number of accidents can be avoided if judicious choice, proper training and proper care be given the animals. Those animals which attract attention on the surface because of their animation, cavorting, and appearance, are treated kindly, are properly fed, watered, and well groomed, consequently the adage "A horse is what you make it" is as applicable to underground animals as those which live and work above ground.

In purchasing stock for underground haulage, activity, eyesight, feet, temperament, strength, and wind are considerations, but if the animal lacks intelligence he has no place in the mine.

It is natural for the farmer or teamster who has an occasional animal to sell to dwell on its good points, neglecting the bad. The dealer's talk may therefore be eliminated beyond the soundness of the animal, and the acceptance or rejection simmered down to the use of one's judgment. In most instances it is better to deal with those who make a business of furnishing mules to mining companies, and if it is possible, to go to the stock yards and pick out the animals rather than trust to the dealer's judgment. This suggestion is made because the dealer scarcely knows more about the animals than the purchaser, and does not know the conditions under which the animals must work. Again the dealer, anxious to retain the trade of the purchaser, will send a nice looking animal which is probably everything a farm mule should be for soundness and strength, yet lacking in the most important necessary points for mine haulage; namely, activity and brains.

Many animals which act and look right on the surface are most unsatisfactory underground, for which reason the suggestion is made that after the animals are picked out an agreement should be made with the dealer that in case any of them do not act rightly in the mine they may be exchanged. If mine stock can be purchased near the mine it can be trained as soon as received. If, however, it has been subjected to a long car journey, 3 or 4 days should elapse before an attempt is made to take it in the mine. In the meantime the animals should be placed in the paddock to allow them time to get over their transportation legs, rest up, and get acclimated. At the same time they should be examined to see that they have not contracted influenza, pink-eye, or some other disease on the journey.

During the first 2 or 3 days the animals are put to work in the mines they should be in the hands of capable handlers and trainers, because being usually green and soft, they may be readily scared and made mean. It is stated that any habits incurred by mules during this training period are difficult to eradicate, and in almost every instance mules that are properly handled at the beginning of their underground careers are the most tractable. By nagging and abuse it is possible to spoil the temper of an animal as well as a child, and frequently a mule will resent this treatment to the best of his ability; therefore, nearly every coal-mining state will report deaths due to mine mules.

While a mule's heels are not to be trusted, nevertheless the humane driver and his mule become good chums. If, after a 3-day training period the mule does not appear active on his feet and to use judgment, he should be taken from the mine, as he is unsuited to the work and cannot be depended upon to look out for himself when occasion demands. It is believed that if this suggestion is followed many mules' lives will be saved. Next to animal intelligence as a means of saving mule life, is its care. Animals that work in mines should have clean comfortable quarters, with pure water and good wholesome food; nor is this all, they should have their feet and legs washed regularly and their hocks dried and their bodies should be as regularly combed. At large operations it is customary to keep a veterinary, who examines the animals that are well and treats those that become sick. To those who are unable to incur such expense, it may be stated that stock well fed, groomed, and housed, will, if in good health, enter into the spirt of hustling with as much zest as the drivers; but if abused, neglected, or feeling unwell there is danger of their losing interest in the work and becoming injured. A mule that is not feeling well should not be worked, and a sick mule should be taken from the mine. If it be possible the mules should be taken from the mines every Saturday and returned Monday morning before daylight; that is, if it is not the custom to hoist them out every day.

Fig. 1. Underground Stable, Western Pennsylvania

Few mining men not directly connected with large shaft operations realize the magnitude or the initial cost of a modern underground stable. Shaft operations, once confined to the anthracite collieries in the United States, have become so extensive in the bituminous fields that in most cases the old practice of lowering and hoisting the live stock has been abandoned, and the horses and mules are provided with quarters even more comfortable and commodious than those of the live stock that are stabled outside the mines. The underground stable, shown in Fig. 1, is reproduced from a flash-light exposure made 330 feet below the surface in one of the best constructed underground stables in the bituminous coal region of Western Pennsylvania. The stable is 18 feet wide, 12 feet high, and long enough to accommodate 50 head of stock. It is constructed of red brick, and the walls and arched roof are frequently whitewashed. It is built immediately in the 8-foot seam of coal, and is lighted with incandescent lamps, ventilated by a current of fresh air which does not traverse any other portion of the mine, and is

* Literature in Mines and Minerals: "Pit Stock and Management," J. W. Byers, Vol. XXIII, p. 295. "Care and Protection of Mules in Mines; Rules issued by D. & H. Coal Co.," Vol. XXIII, p. 568. "Nutriotone," Vol. XXIII, p. 272. "Bickmore Gall Cure," Vol. XXIV, p. 491. "Care of Mine Mules," Dr. J. C. Newhard, Vol. XXVIII, p. 56. "Care of Mules' Feet," Vol. XXX, p. 435.

supplied with fresh water brought down from the surface through a pipe. It contains a hospital stall for sick or crippled animals. While it is customary to have a sanitarium for mules underground, it is unquestionably better to remove the sick or injured animal to a hospital outside the mine. Disease and wounds always do better where there is fresh air and sunshine.

The stable ventilation should be watched, as the mules are subjected to more or less impure air all day, and while fresh air is good for the animals, nevertheless, they should not be subjected to drafts, particularly after coming from work when they are warm. The stable boss takes pride in keeping his animals in good condition; therefore, it is discouraging when a mine foreman will permit drivers to abuse them. When a mule comes to the stable in the evening showing whip marks and bruises the stable boss should not allow this driver to have another animal until the case has been investigated. There is no reason for abusing an animal with a whip, particularly when pulling at its best, and it is an incompetent foreman that will permit such treatment. It is the duty of the stable boss to report the abuse of the mules, and it is the duty of a mine boss to see the mules once in a while as they go out in the morning and return to the stable at night.

Mule Barn in Ross Seam, Truesdale Mine

According to two authorities the animals should be fed as follows: First, hay, next water, and then grain. Animals should eat hay at least half an hour before being given grain. If the water is given last it washes the food into the intestines before it is acted upon by the gastric juices. If the hay is given after the grain it carries the grain with it, for the hay is principally digested in the intestines, while the grain is acted upon by the stomach for the most part.

Corn is richer in fat than oats; therefore, for strength, feed corn, and for speed, feed oats. For an illustration, race horses are fed oats, and the experienced teamster will favor the feeding of corn.

Dr. I. C. Newhard, Chief Veterinarian of the Philadelphia & Reading Coal and Iron Co., experimented with various feeds and found that two-thirds crushed oats and one-third cracked corn the most reliable. "A handful of coarse ground pure salt should be fed to each mule twice a week." Dr. Frank Amos, who is in West Virginia, suggests a coarse-crushed feed, about two-thirds corn and one-third oats.

Mine stock will consume about 12 pounds per head per day of this feed and about 15 pounds of hay. If a horse or a mule has not cleaned up its former feed the troughs should be cleaned and less put in the next time, until it is ascertained just how much it takes to keep them. The animal should have about all it will eat, but it is better to give not quite enough than too much. Too much grain will cause acute indigestion, paralyze the walls of the stomach, and usually results in death. A stable boss will make a great mistake by feeding too much and allowing food to stand before the animals all the time. While this method will increase flesh for a short period the animals eventually break down through their digestive organs being destroyed.

Grain should not be placed in the animals' troughs ready for them when they come in from work, and it is better for them to be without grain at noontime than to be without water, but by all means give them three feeds a day. Plenty of water will keep the digestive organs in good condition, while large quantities of grain and no water will destroy them.

To give a feed of good bran once a week will aid the conditioning of stock, keep the bowels open, and reduce fever, which is caused by strong grain.

The most common troubles which result from high feeding are heaves and affected wind. Horses sometimes die from the effects of a disease known as azoturia, which is caused by idleness and feeding strong grain. Laminitis is more common in mules from long standing on hard floors for several days and being fed the same amount as when at work. This disease can be avoided by reducing the feed and giving some exercise. Time and attention given to this simple treatment by a stable man is profitable, for it is always the largest and best stock which become affected with this disease, and there are few that recover from it.

So far no veterinarian has recommended the use of cut feed with chop as a regular diet, although this feeding is followed in many places.

The P. &. R. C. and I. Co. feed their stock twice daily. Doctors Hogg, Phipps, and Newhard state that "fresh water should be provided in iron, terra-cotta, or concrete troughs in front of the mangers, where the animal has access to it at all times. Where our stables are equipped with a constant supply of fresh water, colic and acute indigestion are unknown."

Frequently a mule is said to be a kicker and dangerous to handle, but after investigation it is found that the animal has been worked with a collar upside down, or the hames back on his shoulders, and that the stable man or mine foreman did not see the animal go out of the barn and knew nothing of it until it came back from work, with sore places on it. An animal working under these conditions should be admired for trying to defend itself, but the results are it must be sold at a great loss or kept at some other work until well. A stable boss or mine foreman should not allow any of his stock to go out of the barn until he sees that they have the harness that belongs to them, and that it fits properly. To obtain good results from animals the harness must be made to feel comfortable and strong on them.

Part of Mule Barn in Clark Vein, Continental Mine

Good judgment should be used in fitting the bridle, collar, hames, and harness. The collar should be neither too large nor too small, and the hames should fit so they will have the right pressure against the shoulders and the traces should be of equal length. If these matters are given close attention many accidents will be avoided, the stock will be more valuable, and help to keep down expenses in various ways.

It is particularly necessary to give the shoeing of stock close attention, for a good foot is the foundation of a good horse. The stable man should examine the feet carefully to see that the shoes are all tight and properly set before he lets the animal go to work. Then again, if the shoe stays on too long it will cause the hoof to expand over the shoe and produce sore heels and corns. When a shoe comes off and is not promptly replaced, the animal's hoof may be so torn that sufficient nails cannot be inserted to hold the shoe, and should this occur several times successively the animal is of no account for mine work because his feet will not stand the strains. When stock is condemned on this account, it is often said they were of no account when purchased.

There are many mules crippled and made unfit for service by ignorant and inexperienced blacksmiths, who do not know the first principle of proper shoeing, and are unable therefore to give proper attention to the animal's feet. Oftentimes when a blacksmith goes to set a shoe he will just rasp the dirt off of the hoof and then place the new shoe on the exact spot where the old one came off. This treatment in time allows the hoof to grow so out of proportion that it is almost impossible for stock to travel at all. Some blacksmiths do not know enough to pare down the hoof so the shoes will rest on the outer horn, which must be done in order to keep the hoofs as nearly natural as possible. Often blacksmiths drive nails through the sensitive tissues of the hoof, which always lames the animal and is often the cause of stock being so badly crippled in a short time that they cannot be longer used in mine work.

The animals' feet should be kept thoroughly clean, and when they commence gettting hard or become feverish, they should be made to stand in clean, not acid, water at least 2 hours per day until the feet are softened and regain their natural condition.

Quite a number of horses and mules need not be condemned if these comparatively simple matters are given attention.

Having disposed of the subject of crippled stock from the effects of bad shoeing, attention is next directed to making good roads, and this in the judgment of some is the most important question on the inside of the mines. The stock is compelled to travel in mines with very little light, and it is reasonable to suppose that with smooth roads and cars kept well oiled, more can be accomplished with fewer accidents, and a better general condition of the stock maintained. If there are rocks and lumps of slate in holes between the ties, the stable bosses have a good excuse for not being able to keep their animals' legs in good condition. They cannot heal bruised knees caused from stumbling over the ties, nor bruised heels and skinned ankles in one night's time. Often there is a mule brought out on a truck dead, the driver saying he could not get the brake to work, or that the bits on the mining machines caught them and almost tore their legs off. These reports are frequent ones and are not always to be believed if they come from the driver alone, for they make reports of this kind because they have become common; a driver who thus reports should not be allowed a horse or mule until the case has been thoroughly investigated, and the cause remedied, so the same thing will not again occur.

The Fairmont Coal Co.'s records for 1905 show that 26 per cent. of their stock either died, was killed, or had to be disposed of at practically nothing, on account of being crippled and worn out. There is probably no part of the company's business in which the loss is so great, and one-half of this is brought about by carelessness and neglect. There is probably no other business that requires the use of stock in which the loss is so great, and this in face of the fact that the facilities furnished, with the exception possibly of good roads inside the mines, are the best that can be had.

The daily grooming of mine stock is important. It has a tendency to keep the body in better health and causes the mules to be more alert.

Doctor Newhard has introduced a vacuum grooming machine with excellent results at the St. Nicholas colliery stables.

Not more than three mules should be in a string team, as four or five mules cannot be handled successfully by any driver.

Oftentimes bad teeth are the cause of an animal being sluggish and in poor condition; therefore, competent veterinarians should look after the teeth of mine mules once every 2 years.

The maintaining of live stock is no little item, and in cases there is an average of 5 per cent. of the total number of animals standing in the barns all the time unfit for service on account of having been crippled. The feed for this stock, besides other expenses and the loss of their work, costs one company over $6,000 per year.

Where mine stock is given good attention, the upkeep is reduced to a minimum, more work is obtained, and the animals are more valuable. As the methods suggested are reasonable and simple, it is to be hoped that they will be followed by all persons interested in prolonging the lives of mine stock.

OBITUARY

SAMUEL CALVIN

Prof. Samuel Calvin, M. A., Ph. D., LL. D., F. G. S. A., head of the Department of Geology of the State University of Iowa, died at his home in Iowa City, April 17, from dilation of the heart. He was born in Wintonshire, Scotland, February 2, 1840, and came to this country in 1852. He became Professor of Geology at the State University of Iowa in 1874.

Professor Calvin was one of the foremost scientists of the United States, and was recognized in certain fields of geological activity as the world's authority. He was the editor and associate editor of the *American Geologist* from 1888 to 1905, retiring on account of other work. He was a fellow of the American Association for the Advancement of Science, being elected president in 1894. He was a fellow in the Geological Association of America, of which he was president in 1908. He was made State Geologist of Iowa in 1892 and held this position at the time of his death. President Roosevelt chose him as one of the members of the White House conference on the conservation of the natural resources of the United States in 1908. He was a member of the Government Advisory Board on Fuels and Structural Materials, and has written extensively on these subjects. He published quite extensively on the Pleistocene geological period in Iowa, and is considered the authority on this subject. He is made famous the world over for his work on Paleontology. To all Iowa students he is known as "The Grand Old Man of Iowa."

The electrical horsepower consumed by direct-current motor is found from the following formula:

$$\frac{V \times A}{746}$$

Where V = volts; A = amperes; 746 = number of watts in 1 horsepower.

Example: A direct-current motor is using 250 volts, 100 amperes, what is the horsepower consumed? Substituting in above:

$$\frac{250 \times 100}{746} = 33.5 \text{ horsepower.}$$

THE COAL MINES OF DAWSON, N. MEX.

*By Jo. E. Sheridan, Silver City, N. Mex.**

A Description of the Plant of the Stag Cañon Fuel Co. and the Methods of Management and Operation.

The Dawson coal mines are owned and operated by the Stag Cañon Fuel Co., of which Dr. James Douglas is president and E. L. Carpenter general manager. The mines are in the southern end of the Raton coal field, which extends north from Colfax County, N. Mex., into Colorado and embraces the coal mines of the Trinidad section.

The coal measures, known as the Laramie series of the Cretaceous system, have a thickness of about 800 feet in the vicinity of Dawson.

The coal makes an excellent coke. There are but few dikes in the southern portion of the field and little or no faulting along the dikes. There is but little disturbance of the strata throughout the Raton coal field in as far as it extends into New Mexico. table land has been eroded, exposing the green shales below the coal measures, and leaving a bold escarpment along the entire side, whereon each stratum and coal seam is distinctly identified. The Vermejo River and a few small cañons or gulches intersect the land in such manner as to expose a crop line which aggregates a length of about 40 miles. From these exposures the coal seam may be developed by as many openings as are necessary to supply the demand for the product. At present five openings are in operation, known as mines Nos. 1, 2, 4, 5, and 6. Mines Nos. 3 and 5 were connected by entries more than a mile long, between Rail cañon and the Vermejo River. Mines Nos. 1 and 2, located in Rail cañon, have entries driven into the coal for more than a mile; the coal at the faces shows a thickness of 8 feet 4 inches, and is apparently cleaner than that near the outcrop. All of the mines are opened by drifts, which are rendered practicable owing to the continuous outcrop of the coal and the easy and constant dip of the seam, from N 10° W to N 30° W.

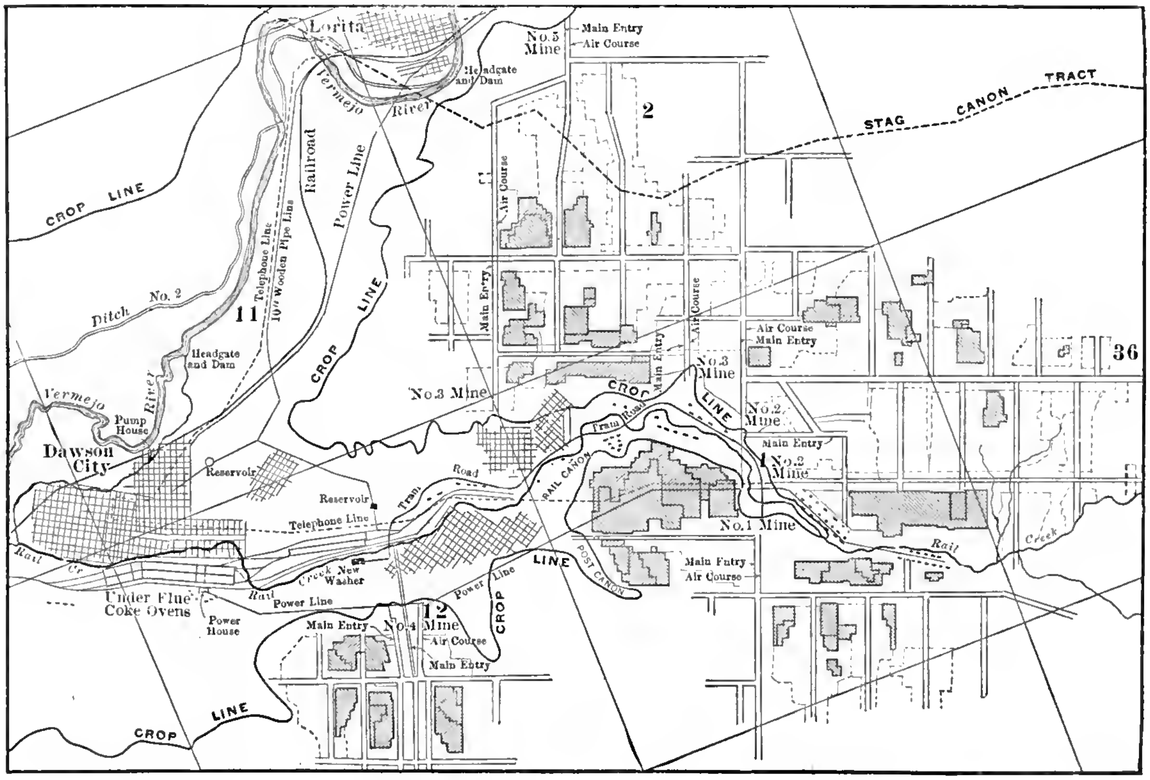

Fig. 1. Working Plan of the Stag Canon Fuel Co.'s Mines, Nos. 1, 2, 3, 4, 5, and 6, Colfax County, N. M.

There are two workable seams in the coal measures, and two or three smaller coal seams, ranging from 1 to 2.5 feet in thickness. The Dawson mines are located upon the lower of the two workable seams, which is known as the Raton or Blossburg seam.

The Stag Cañon Fuel Co. owns about 38,300 acres of land underlain by this great coal seam. In the Dawson mines the thickness of the developed seam varies from 6 to 11 feet, with an average of at least 7 feet. Computing the tonnage which may be recovered upon the usual basis of 100 tons per inch of thickness per acre, there are 321,720,000 tons of coal in the property, and deducting 20 per cent., or 64,344,000 tons, for eroded gulches and insurance against unforseen losses, such as mine fires, squeezes, and other unfortunate conditions, there remains 257,376,000 tons to be recovered.

The topography of the field favors the economical and rapid development of the coal. The eastern projection of the elevated

* Territorial Mine Inspector. Transactions of the American Institute of Mining Engineers

The system of mining is by triple main entries, double cross-entries, room and pillar, and robbing on retreat, when the district becomes exhausted. The width of main entries and cross-entries and air-courses is 9 feet; the height of air-courses, 6 feet 6 inches; the height of roads, 6 feet; room necks are 20 feet long; average width of rooms, 24 feet; average length of rooms, 350 feet; distance between room centers, 50 feet. The coal is hauled by mules from the rooms to the partings within the mine, whence it is brought to the outside yards by electric locomotives, of which there are 10, of the Jeffrey, Westinghouse, and Goodman types. A system of electric signal lights is used, a red light hanging beside the regular mine light. As the motor enters each block a red light is turned on automatically to give warning that a car is coming on that block. Mines Nos. 1 and 2 are ventilated by two Vulcan fans, 24 ft. × 8 ft., exhausting, but reversible. These fans are driven by two 50-horsepower alternating-current induction motors of slip ring, variable-speed type. There are also auxiliary, direct-current 50-horsepower motors, which can be run independently in case

of emergency. Each fan, operating at 60 revolutions per minute, and a pressure of 1.2 inches water gauge, produces an intake ventilating current of about 80,000 cubic feet per minute. Mines Nos. 4 and 5 are ventilated by two Cole 15-foot diameter straight-vane fans.

The following data, pertaining to the operation of mines Nos. 1, 2, 4, and 5, are of interest: Average number of miners on the pay roll, 700; average number in the mines each day, 620; number of company men constantly employed underground, including drivers, trappers, timber men, fire bosses, motor men, and pit bosses, 115; the total air-intake averages 260,558 cubic feet per minute; 59 mules are used for gathering the coal from rooms to the partings; and allowing 600 cubic feet of air per minute for each mule, or 35,400 cubic feet for 59 mules, there remains for the use of the 735 men underground 225,158 cubic feet of air per minute, or 306 cubic feet per minute for each man employed. The water gauge varies from .8 inch in No. 4 mine, with the shortest pull, to 1.2 inches at No. 2 mine, the longest pull. The air measurement is given in the aggregate, for brevity, but each mine has its proportionate share for persons underground, which amounts to three times the quantity required under the United States law governing the operation of mines in the Territory.

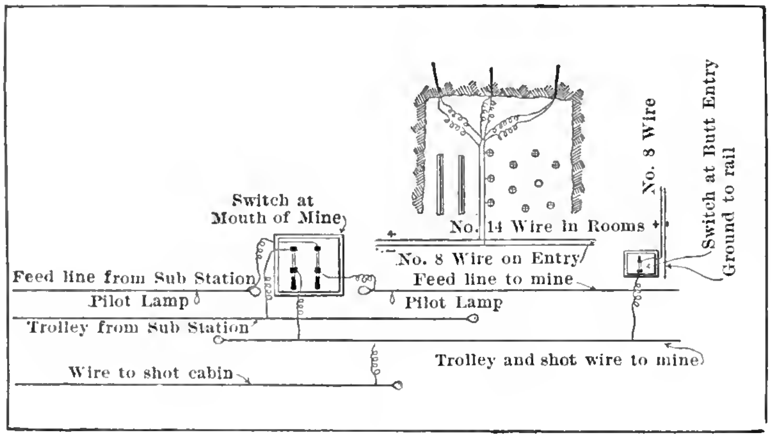

Fig. 2. Diagram of Shot-Firing System in Dawson Mine

About April 1, 1909, an air-shaft will be sunk from the surface at a point 1 mile north from the mouth of mine No. 2. This shaft will be 12 ft. × 12 ft. in the clear, and 250 feet in depth to the intersection of the main return air-course of mines Nos. 2 and 5. A fan of large capacity will be installed at the top of the shaft, exhausting through the shaft, the present openings to be used as intakes.

From mines Nos. 1 and 2 the coal is conveyed to the tipple in mine cars over a tramway 6,600 feet long, which has a rise of 112 feet from the tipple to the mines. Six locomotives haul these cars, as follows: Two 28-ton Porters, one 20-ton Vulcan, one 18-ton Lima, and two 6-ton Porters. The tipple contains a double Phillips dumper, with two chutes for loading railroad cars; the tipple equipment also includes stationary and shaking screens, for sizing coal for various purposes, also a moving slate-picking table.

The coal from mine No. 4, which is located immediately opposite the tipple of mines Nos. 1 and 2, is delivered over a steel Phillips tipple abutting the tipple of mines Nos. 1 and 2. At mines Nos. 5 and 6, the coal is screened as it is dumped on to railroad cars, the slack being hauled to the slack bin, whence it is elevated to a belt traveling to the washery storage bins.

A complete telephone system, having stations at the most convenient points within the mine, affords communication with every important place in the camp, and through the central station with Santa Fe, Albuquerque, Denver, and other cities.

The mines are sprinkled by water cars to lay the coal dust, which is removed from the roadways, as far as practicable, and taken out of the mine. Extra fire bosses have recently been employed at each of the mines to instruct the men in regard to timbering and to see that every precaution is taken to guard against accident from careless work by the miners.

The following rules and regulations have been adopted by the Stag Cañon Fuel Co. for the government and operation of its mines, and distributed to the employes in convenient pamphlet form under date of August 3, 1908:

1. It shall be the duty of each and every employe of this company to inform himself in reference to his duties under the mining laws of this Territory and to comply strictly therewith.

2. No person in a state of intoxication shall be allowed on any of the works, or allowed to enter any of the mines, under penalty of prosecution for trespass under the law.

3. No person or persons shall be allowed to enter any mine except he be a regular employe of that mine, or unless he has a permit from the mine foreman or superintendent.

4. Persons seeking employment shall procure it outside of mine. No boy under twelve (12) years of age shall be permitted to work in any mine.

5. If any person rides upon or in the mine cars going in or out of the mine or on the tram road, he does so at his own risk.

6. All persons, except those duly authorized, are forbidden to meddle or tamper in any way with any electric lights, switches, signal wires, or shooting wires in or about the mines.

7. No person or persons shall go into abandoned parts of any mine unless permission be granted by the mine foreman.

8. All persons before entering the mine must deposit a check at check-house, and get the same when they come out of the mine.

9. The fire boss shall make, before any person is allowed to enter the mine, a careful inspection, with a safety lamp, of

Fig. 3. General View of Washery and Tipples at Stag Canon Fuel Co.'s Mines, Dawson, N. M.

every working place in the mine, marking the day of the month on the face of the coal in each working place where it can be readily seen. If dangerous gases are found in any working place he will mark on a cap piece or shovel two large crosses with the day of the month between them, thus: X27X, and will place these marks so that it will be impossible for any one to pass them without seeing them.

If a quantity of gas is found, which, in the opinion of the fire boss, would endanger the operation of the mine, he is authorized to close the entire mine or any part of it he thinks endangered. The fire boss must always be on the safe side. The fire boss must not allow gas to be moved where men are working in the return air from it.

After complete examination of the mine has been made the fire boss shall come out of the mine and make a report in Report Book of all dangerous conditions found, which report must be read by the mine foreman before any men are allowed to enter the mine. The fire boss shall remain at mouth of mine, or some convenient place, until all the men have entered the mine, instructing each man as to the condition of his working place.

The fire boss must make an inspection at least once a week of all old or abandoned parts of the mine and report conditions of same in Report Book.

10. The mine foremen shall familiarize themselves with the mining laws of the Territory, and shall comply with the requirements thereof by discharging every duty imposed upon them by law and by the rules of the corporation.

11. They shall visit each working place at least once every week and direct the miners and all other employes in their work, and see that their instructions are complied with. They shall direct the miners to securely prop their working places and see that breakthroughs are driven at proper distances. They shall see that the ventilation of the mine is kept in good condition and that all dangerous conditions are removed as soon as possible. They shall have absolute authority over all underground employes, and shall see that all the rules and regulations are carefully carried out.

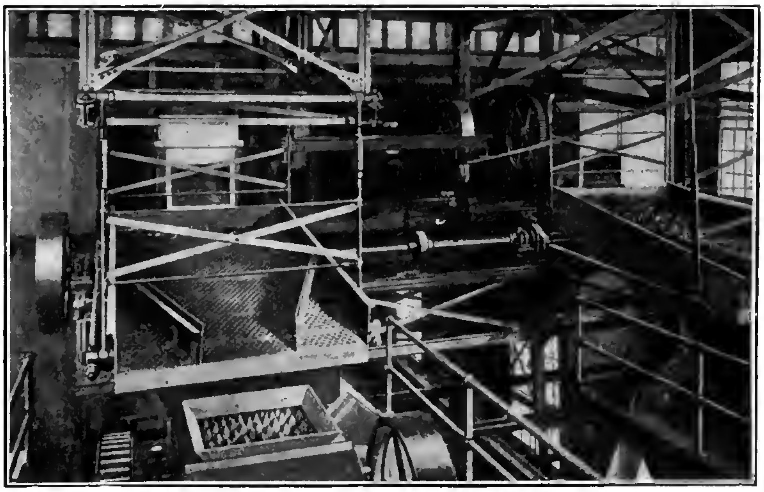

FIG. 4. INTERIOR OF CRUSHER HOUSE, SHOWING SCREENS AND ROLLS

12. All employes shall use every precaution to prevent accidents in or about the mine; they shall not work in an unsafe place when timber would remedy the danger. If timber is not at hand they must stop work and report the fact to the mine foreman. The miner shall each day, before beginning work, examine his working place and take down all dangerous rock, or otherwise make it safe by properly timbering, and shall carefully sprag the coal when undermining.

13. No miner or other employe shall be permitted to burn kerosene, black strap, or machine oil in his lamp.

14. It shall be the duty of every miner to ascertain from the fire boss the condition of his working place before entering the mine.

15. It shall be the duty of the wireman to see that all the employes are out of the mine and the power cut off the mine before he enters the mine to connect up shooting circuits, and to see that all shooting circuits are disconnected from power lines after shots have been fired; also to see that shooting lines are kept up in good shape and that miners are furnished wire for extensions, and to see that all wire is removed from pillars and abandoned places.

He shall make daily report in Record Book of the cutting out and cutting in of shooting circuits.

SHOOTING REGULATIONS

The following regulations for drilling and charging shot holes, mining and cutting the coal, will hereafter be in effect at Dawson mines, and must be strictly carried out by all parties:

1. The mining or cutting must extend at least 6 inches beyond back of holes in all cases.

2. All holes must be at least $2\frac{1}{2}$ feet in length; no shorter holes will be fired.

3. All coal dust must be extracted from holes before they are charged.

4. No holes must be charged with more than five (5) sticks of powder.

5. Standing holes, or parts of standing holes, must not be recharged.

6. The hole in a tight corner must be at least 1 foot from rib at back end of hole.

7. In solid faces, holes must not be more than six (6) feet apart horizontally, and not less than two such holes shall be fired.

8. The object of these rules is to prevent and remove the danger from blown-out or windy shots, and it shall be the duty of the shot inspectors, in addition to the above rules, to refuse to shoot any holes which, in their judgment, may be dangerous, whether the circumstances are fully covered by the rules or not.

9. When giant powder is used in mines not more than fifteen (15) sticks must be taken in the mine for any one working place for any one shift, and in no place must there be more than twenty (20) sticks at any one time.

10. No giant powder must be taken in the mine in a frozen condition, and any attempt to thaw it out in the mine is strictly prohibited. Miners must have their powder supplied to them at the proper temperature to be exploded. Miners are prohibited from accepting, and powder men forbidden from giving out, powder in a frozen condition, and shot inspectors are hereby made responsible for the strict carrying out of this rule.

11. Giant caps must not be kept in the mine; the shot inspectors will give them out to the men, one for each shot, as they are needed, and personally supervise the placing of them in the hole with the powder. Under no condition must they be kept with the giant powder.

12. The powder man will not give giant powder to any person not supplied with a canvas bag in which to carry it.

13. Mine foremen, shot inspectors, powder men, and all others connected with the handling of giant powder going into the mine, must personally see that the above rules are carried out, as far as their supervision in the matter extends.

14. No intemperate man or habitual smoker must be employed as powder man, and, when on duty at the powder magazine, the powder man must not have on or about his person, in the magazine, any pipe, tobacco in any form, or matches, nor any tools or materials from which a spark might be emitted or a light created.

15. When powder is being given out to the miners no one

but the powder man must be inside the magazine, and no person must be allowed around the door of the magazine with a light or while smoking.

16. The presence of women, children, or any person under 18 years of age in or around the magazine is prohibited at all times; also their employment in handling powder, and no powder shall be given out to them.

The shooting is done by electricity after all the men are checked out of the mine. As the men enter the mine they are required to deposit a metal check at the shot-firing house outside, near the entrance to the mine. These checks are placed on a check-board and returned to the men as they come from the mine. A record of the working place of each check number is kept in the shot-firing house, and in case any check is uncalled for, the shot firer makes a search for the man until he is found. No shots are fired until it is known positively that no one is in the mine. The method of placing the shots is shown in Fig. 2.

To insure safety against accidental discharge of the shots by electricity, there are two or more locked switch boxes in each mine, with throw-off switches, one at the mouth of the mine and at one or more stations inside the mine. After inspecting the inside connections with the shots to be fired, the shot firer en route from the mine makes connection at each of the switches mentioned. He then goes to the shot-firing cabin to turn on the electric current, but before doing so he turns on an electric signal light in a red globe, to warn all persons to remain away from the vicinity of the mouth of the mine; so that should an explosion occur within the mine, no one outside could be injured by flying debris. The shot-firing system has proved a success; the safety of the men from disastrous dust explosions due to blown-out shots is assured; miners make better wages, and the production of coal is proportionately greater per man employed. A record is kept of the number of shots fired, showing less than 2 per cent. of missed shots. The missed shots are left for the next day's shooting, and are either reprimed or a new hole drilled to perform the work intended for the original shot. Very little firedamp has been encountered thus far in the mines; but a supply of safety lamps is kept ready for use.

Fig. 5. Hutches from Four Stewart Jigs and Discharge Pipes for Refuse

A Babcock two-cylinder chemical fire engine is kept on a side track, under cover, ready for instant use; also portable chemical fire extinguishers, and helmets of various types to supply means of respiration in any vitiated atmosphere. Hose reels, each carrying 500 feet of best grade of fire-hose, are kept at stations throughout the camp, and a man is employed to inspect daily the hose and fire-fighting appliances.

An organized first-aid corps has had regular practice and competitive drills during the past year, for which the company contributed appropriate prizes and medals for the most efficient team work.

A large building is being erected for a rescue station in which the first-aid corps and others may practice and exercise while wearing the helmets in a chamber filled with vitiated gases. An instructor watches the men, and on showing any signs of exhaustion they will be quickly removed and the gases dispelled from the chamber by suitable outlets. After sufficient experimental work to demonstrate which type of helmet is best adapted to the needs of the mines, a supply will be purchased for use in cases of emergency.

The rescue station is designed after plans of the one in use at the mine of the Dominion Coal Co., in Nova Scotia, modified to some extent. In the upper story of this building there will be a technical library on coal mining, and a "School of Mines" will be conducted by a competent instructor. The superintendents, pit bosses, fire bosses, and others occupying responsible positions in the mines will be required to pass an examination, and if not proficient in the technical and theoretical studies pertaining to their respective positions, as well as in the practical application of these studies, they will be given 6 months in which to perfect themselves. If after this time, they are still deficient, they will be reduced in rank or discharged. It is the aim of the company to introduce and maintain such an excellent standard that a certificate to a graduate of the Dawson School of Mines will be recognized as a guarantee of competency.

The powder magazines at the mines, built of stone, iron, and cement, are absolutely fireproof. The heat is supplied by electric radiators, which maintain a constant temperature within the magazine; the electric stove or radiator and all wires are at a considerable distance from the stored powder, and out of reach of anything combustible or explosive.

The main building of the coal-washing plant is 112 feet long, 70 feet wide, and 70 feet high, and the laboratory and crusher building, are absolutely fireproof, being built throughout of reinforced concrete and structural steel.

Starting at the tipple, the undersize coal from the Nos. 1 and 2 tipple screens is delivered on a 28-inch cross-belt conveyer, running at right angles to the main belt, and carried to a 36-inch belt conveyer. Another 28-inch belt conveyer delivers the slack from the screens of No. 4 tipple to the same 36-inch belt conveyer, and an elevator carries the slack from mine No. 5 slack bin to join the undersize from the other mines on the 36-inch belt conveyer, which conveys the whole to the two 1,000-ton storage tanks, each 40 feet in diameter and 40 feet high. These storage tanks guarantee a constant supply to the crusher house and washery, so that they are not dependent upon the work of the tipples.

Under the storage tanks are two 28-inch parallel belts, upon which the slack coal is delivered from the storage tanks, through eight rocker-gate, adjustable automatic feeders, and conveyed by these belts to the crusher house, where it drops from the belts upon two $6' \times 12'$ shaking screens, about 1.5 inches slope to the foot, .5-inch plate, with 1.5-inch round perforations. The oversize is delivered to two 32-inch toothed rolls, making 125 revolutions per minute and having 100 tons per hour capacity, shown in Fig. 4, which reduce the material to 1.25-inch size to correspond to the sizing of the shaking screen above. The two 28-inch belts and the screens and

rolls are driven by an 85-horsepower General Electric motor. The product from the screens and rolls is deposited upon a 30-inch belt conveyer, which carries it to the dust-proof room on the third floor of the washery. As this belt with its load of slack leaves the crusher house en route to dust-proof room, each 25-foot section is automatically weighed and recorded by a Blake-Dennison automatic and continuous weighing machine. Thus the data of results are based upon accurate figures. This belt is 278 feet long, center to center, 76 feet 8 inches rise, has a capacity of 250 tons per hour, and is driven by a 50-horsepower Western Electric motor.

In the dust-proof room water is added by two 5-inch centrifugal pumps to the crushed coal, and the whole is carried in launders to eight jigs of the Stewart type, two double jigs on each side of jig floor. The jig and water-supply tanks are of steel plate, concrete lined. The pumps which supply water to these jigs are driven by two 50-horsepower Western Electric motors.

From the dust-proof room onward the washery plant is built in two units on the east and west sections of the building, and operated independently or together, so that an accident on one side offers no hindrance to the continued operation of the other half of the plant.

The hutches of the jigs, Fig. 5, taper downward, and are connected with two Luhrig elevators by 8-inch pipes. These elevators discharge the refuse into launders, which deliver it to two refuse trommels 4 ft.×8 ft. All trommels have $\frac{5}{16}$-inch perforations, $\frac{3}{16}$-inch plate, 1.5-inch slope to the foot, and are operated at a speed of 17 revolutions per minute.

The oversize from the refuse trommels passes to rewash jigs of the Stewart type; the undersize is rewashed in four Luhrig jigs, two on each side; the recovery from these jigs joins the washed coal from the primary Stewart jigs, and is conveyed by launders under the jig floor to four dewatering trommels, two on each side, the oversize from which is spouted into two 60-inch Steadman disintegrators, operated at 325 revolutions per minute, where it is crushed to desired size for coke ovens. The east and west side sections of the jigs are each driven by an 85-horsepower General Electric motor.

The undersize from the trommels is recovered from settling tanks beneath by perforated-bucket elevators running 15 feet per minute; and, together with the washed coal from the Stewart and Luhrig jigs, is delivered to a conveyer belt traveling 287 feet 3 inches, to seven 300-ton cylindrical steel storage tanks, each 20 feet in diameter, 40 feet high, and distributed by two drag conveyers operating above the bins, whence it is taken by electric larries to the coke ovens. The rejected material from the various washings and rewashings is picked up by elevators and discharged into the waste tank at the south end of the washery building, whence it is taken by electric trolley cars to the waste dump.

The recovery from the oversize from the refuse trommels carried to Stewart rewash jigs is a product equal in fuel value to the unwashed mine product, and is used as nut coal for domestic or steam purposes. This material is carried by belt conveyer to a circular steel storage bin.

Twenty-seven electric motors, having an aggregate capacity of 1,159 horsepower, are operated in conveying the coal from the tipple and through the crusher house and washery until delivered in the washed-coal storage bins. All motors on the alternation current are three-phase, 25-cycle, 220-volts.

An adjunct common to the mine tipple of mines Nos. 1 and 2 and to the washery is the "run-of-mine" crusher situated at the tipple. The crusher is a McCully gyratory, with a capacity of 200 tons per hour. Should there be any temporary cessation of orders for screened coal for commercial purposes, the whole product of these mines could be crushed and conveyed to the storage bins to be washed and made into coke.

The washery has proved an eminent success. Even in the experimental stage the fuel value of the waste was as low as 8 per cent., and the average loss of fuel values in the waste from the washery now and hereafter will probably be below 5 per cent. The capacity of the plant is 2,500 tons per day of 10 hours, but as there are not a sufficient number of coke ovens erected to utilize this tonnage, the plant has never exceeded 8 hours in constant operation. The washery is located in Rail cañon, at a common center to the greatest area of the coal lands of the company.

A complete laboratory is in a two-story concrete and iron fireproof building, 38 ft.×26 ft. 6 in., opening into the main washery building. The lower story is used for grinding and preparing for analysis samples of coal, coke, bone, and waste; the upper story contains the laboratory proper, which is fully equipped with every modern appliance necessary for the work at hand.

All of the machinery for handling the unwashed coal, jigs, and other appliances used in the washing, as well as machinery for handling the washed coal, was manufactured by the Jeffrey Mfg. Co.

FIG. 6. DEWATERING TROMMELS

OBSTACLES TO DEVELOPMENT OF ALASKAN COALS

Two influences have held back the development of the Bering River and Matanuska fields. One has been the advances made in the California oil districts, and the other the unfortunate conditions existing in regard to the laws under which Alaska coal lands can be taken up.

During the decade ending with 1908 the annual output of the California oil fields increased from about 2,500,000 to nearly 45,000,000 barrels. As probably 80 per cent. of this petroleum is used for fuel in the Pacific coast states, it has to a corresponding extent decreased the demand for coal.

A far more serious handicap has been the coal-land laws. Though laws intended to enable the individual to obtain title to coal lands have been on the statute books for the last decade, not a single acre of land has yet gone to patent. It is therefore not surprising that progress has been checked in the coal fields and that many who would undertake their development have become discouraged.—*United States Geological Survey.*

THE COKEDALE, COLO., EXPLOSION

Written for Mines and Minerals, by Geo. F. Duck

Conditions Existing in the Mine After the Explosion and the Conclusions to Be Drawn from Them

A few minutes before 9 P. M., February 9, 1911, a quantity of 40-per-cent. dynamite left behind by the shot firers near the face of the twenty-first room on the first west B entry of the Cokedale mine of the Carbon Coal and Coke Co., 8 miles west of Trinidad, Colo., exploded through the agency of a blown-out shot.

In this as in other similar accidents in which large loss of life and destruction of property resulted, care must be taken to distinguish between the initial and secondary or propagating causes. It would seem that the various initial causes have been exhausted in the recent explosions in Colorado. At Primero on January 31, 1910, the explosion, so far as known, was due to marsh gas; at Starkville, on October 8 of the same year, to an electric arc brought about by the short circuiting of the trolley wires; at Delagua, on November 8, to an underground fire; and at Cokedale, on February 9, 1911, to the explosion of dynamite.

In each of the above cases the destruction of life and property by the initial cause and at the focus of the explosion was either nil or relatively insignificant. In no instance would the destruction have extended beyond the point of origin had it not been for the presence of a propagating agent. This agent is found in all these cases in a coal dust high in volatile matter (about 31 per cent.), and of marked and even unusually pronounced coking character.

The Cokedale mine was supposed to be eminently safe and had always been so reported by the state inspectoral staff. It was generally well watered, the ventilation was good, the shot firing system was approved, and inspection was regular and thorough. On the other hand, the mine must have been dusty or the force of the exploding dynamite could not have extended beyond the twenty-first room on the first west B entry.

Two views have been advanced to account for the dust in the Cokedale mine at the time of the explosion. One holds that there was no standing dust generally distributed throughout the workings upon ribs, roof, floor, and timbers, but that all the dust concerned in propagating the explosion of the dynamite was due to that made immediately before and at the time of said explosion by the breaking into minute particles of the very soft coal through abnormally and unusually rapid shot firing.

The second view is the general one; namely, that there was standing dust in the mine and that that actually made by the rapid shooting of the coal played an insignificant part in extending the destructive effects of the exploding dynamite.

Before a decision as to the correctness of either view is permissible, a more detailed study of the conditions prevailing at the time of and immediately prior to the accident must be made.

The surface plant at Cokedale, remarkable in the universal use of concrete, particularly in coke-oven construction, has been described in Mines and Minerals.

The coal seam, which outcrops at the tipple site at the level of the railroad track, varies between 4 feet 6 inches and 8 feet 6 inches in thickness, with a fairly well sustained average of 6 feet. It is a member of the Laramie series of the Cretaceous period and is said to be some 200 feet above the bed worked at Starkville, about 4 miles to the east. The seam is universally divided into two members by a parting slate from 2 inches to 8 inches and more in thickness. The upper member of the seam is soft, friable, and of a texture and structure similar to the Connellsville coal of Pennsylvania The lower member is harder and more blocky. The coal averages about 31 per cent. in volatile matter, and possesses marked coking qualities. The entire output of the mine, amounting to 1,300 tons daily, is washed and subsequently coked in the plant of 350 ovens, the resultant product being shipped to the works of the American Smelting and Refining Co., of which the Carbon Coal and Coke Co. is the fuel end.

At the time of the explosion the average number of men employed underground was 275, and outside, 170.

The mine is divided into panels, known as the A, B, and C blocks, by a series of north and south entries from which west entries are turned at right angles. It will be noted that the panels are all connected by entries or rooms. The entries are usually 6 ft. × 10 ft. with a 25-foot pillar to the parallel entry. The rooms are 300 feet long, 20 to 25 feet wide, with a 25-foot pillar to the next room. Gathering is done by mules, and haulage to the foot of the slope is performed by two small electric motors operated under 240 volts pressure. The slope, which, with the trestle approach to the tipple, is about 600 feet long, is equipped with a chain hoist of 2,200 tons capacity. The entry timbering cannot be too highly commended and is very unusual for a bituminous coal mine.

Because the south entries were driven to their limit before the room entries were turned and because these room entries were also driven to their limit before the first room was turned, the naming and numbering of the entries and rooms is the reverse of that usually followed. The entry most distant from the foot of the slope is numbered one with a letter affixed to denote the block in which it is driven, thus, first west B entry. A portion of the mine beyond the first west B entry is called Japan, by reason of the number of natives of that country working therein.

The men entered at the manway, or fifth east entry, where a careful system of checking in was maintained. By this means, 15 minutes after the accident it was possible to prepare a typewritten list of the men in the mine, together with their age, distinctive marks, next of kin, working place, etc.

The method of mining in rooms is unusual, and may be likened to the bench and heading system familiar in tunnel work, but laid out horizontally in place of vertically. The advantage of this system is that, except in the heading or narrow portion of the room, two free faces are always available to the action of a shot, undercutting being therefore unnecessary. On the other hand, unless carefully watched it is obvious that it lends itself to blown-out shots through misplaced holes having too great a thickness of coal to work against. It is practically impossible to maintain the steps at right angles and with a face of just 6 feet.

In the benches, the holes are placed in vertical pairs near the rib, four being needed to square up the face. In the heading, which varies from 6 to 8 feet in width, the coal is rarely undercut the full height of the upper member of the seam. That is to say, it is top-cut near the roof and not undercut at the floor. When cut the full width of the heading one center shot is relied upon to bring the coal down; when undercut partially, one bottom shot near the floor and under the cutting, combined with a vertical pair near the rib are used, and when not cut at all, which is the usual practice, the customary cut and side shots are used. For the reasons given immediately above, as many as seven shots are not infrequently fired in one room at the same instant.

Ventilation is produced by a 15′×7′ Capell fan which, at 80 revolutions and at .9-inch water gauge was circulating some 55,000 to 60,000 cubic feet of air a minute. The fan is set in reinforced concrete above and to one side of a shaft connected with the third north entry or main return air-course. The return underground, Fig. 1, is driven to the crop where it is closed by double explosion doors. The three points of intake, the direction of the air throughout the workings (indicated by arrows), as well as the location of brattices, regulators, doors, over and undercasts, are shown on the map. An arrow with the letter *E* affixed indicates the direction of advance of the explosive wave.

Two fire bosses are employed who inspect the working

places not more than 3 hours before the men enter and who examine the abandoned portions of the mine once a week. They state that methane is of rare occurrence, although sometimes found at the faces of the advanced workings in the C block. As opposed to this, the analyses by Mr. John B. Ekeley, Professor of Chemistry at the Colorado State University, Boulder, and published in the biennial report of the State Coal Mine Inspector, which appeared April 1, are of interest, as showing and eighth west C entries which served as the return air-course. An electrical shot firing system was used up to within a short time of the accident. At the time of the explosion the mine was divided as nearly as possible into four shot-firing zones, to each of which was assigned a head shot firer and an assistant. In addition there was a boss shot firer whose duties seem indefinite and of no immediate value, as he naturally could be with but one gang at a time. About 5:45 P. M., after

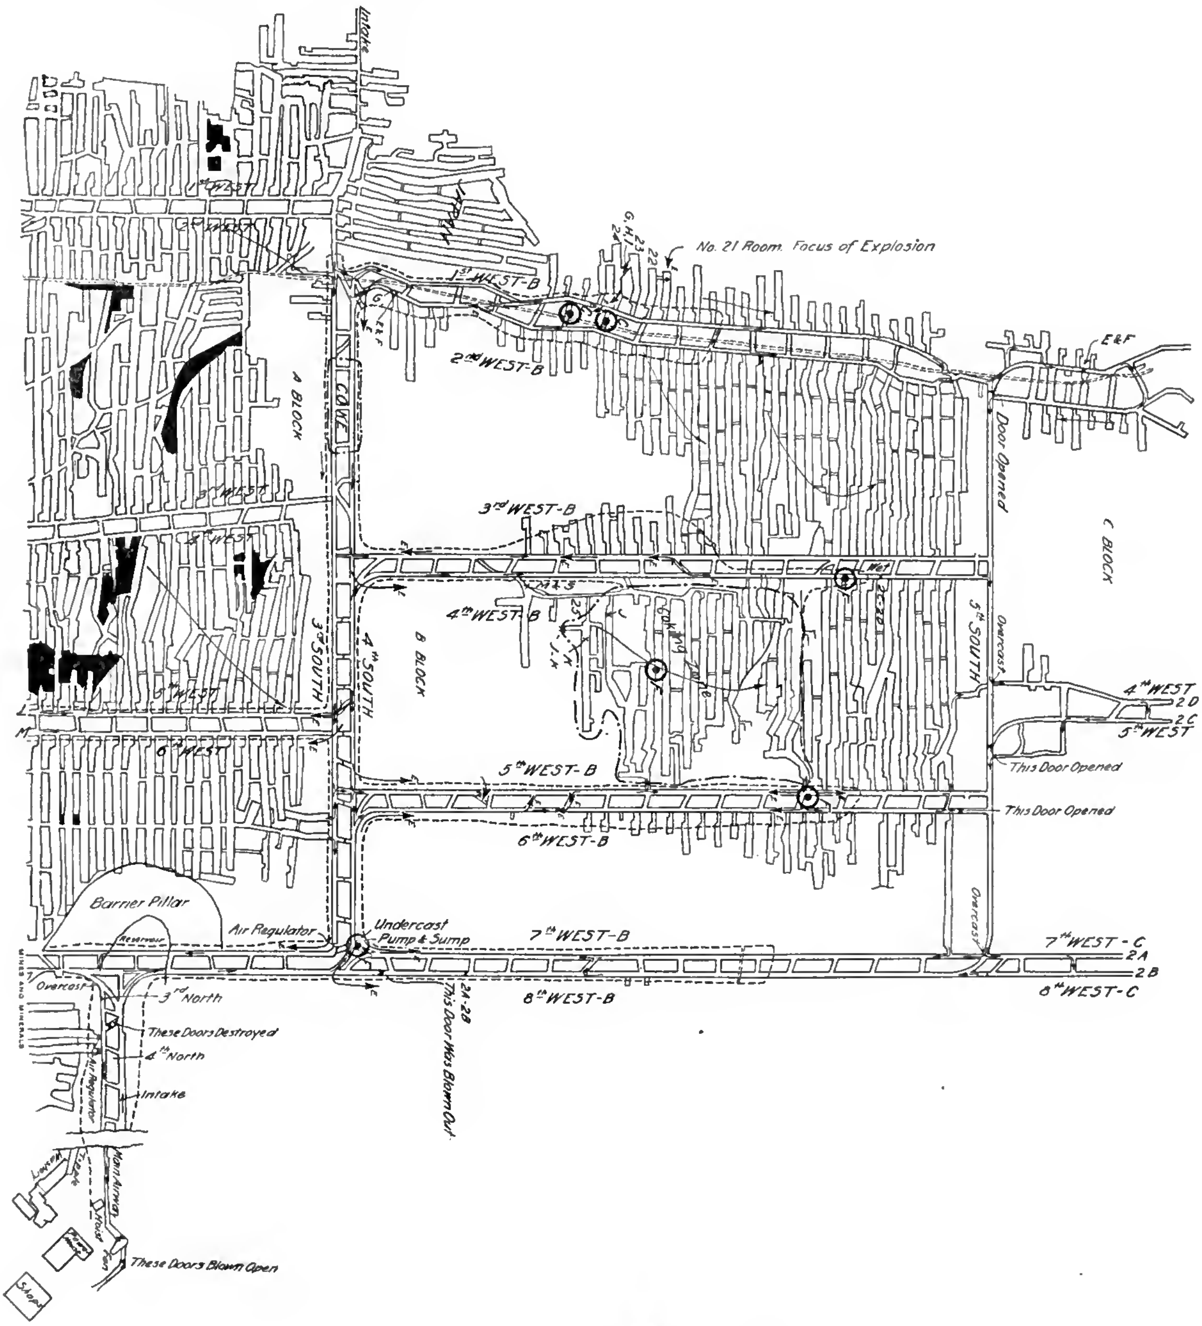

Fig. 1. Map of Part of Mine at Cokedale

the more general presence of gas than suspected. Professor Ekeley found .7 per cent. of CH_4 in the pillars in room 10 on the second west B entry; .8 per cent. at the face of the fifth west C entry, and .4 per cent. in the main return airway in the undercast at the fourth south entry. However, it appears improbable that gas figures either in the origin or propagation of the explosion.

It will be noted that the air-current swept practically all over the mine; that brattices between parallel entries were not usual and that all the air gathered at the in-by end of the seventh the check-board showed that all the men were out of the mine, the shot firing crew met at the small powder magazine on the hill above the manway and received an amount of powder believed to be sufficient for the night's work. This powder, the night of the accident amounting to 648 pounds, was placed in eight or more canvas sacks and loaded into a powder car drawn by a mule. After hanging red lanterns at the mouths of the manway and the main slope the crew entered the mine and at the cap house at the third south entry secured the necessary detonating caps. From a nearby underground telephone,

word was received from the powder house that all current was shut off from the mine. The powder car was then driven into the workings, each shot firer and his assistant removing therefrom at the proper cross-entry the amount of explosive required by them.

When a room was reached the sacks were supposed to be left on the entry, the shot firers taking as much powder to the face in their pockets as they believed would be necessary to charge the holes in the room. At the face, the shot firers were presumed to examine the holes and to reject such as were dirty or tight. After charging and tamping with clay, the procedure varied. In some instances a series of rooms were prepared and the shots fired, room by room, as rapidly as the men could pass from one place to another, while in other cases the room was shot as soon as the holes were ready and then the next room prepared, etc. In no case were sacks of powder to be taken to the face. After all the shots were fired the men left the mine, supposedly about 1 o'clock in the morning, 2 hours before the fire bosses appeared. However, it transpires that the shot firers were rarely in the mine after 11 at night. As it naturally required considerable time to secure the powder and caps, to enter the mine, and to get to the working places and charge the holes, it seems probable that little firing was done before 7. The sustained maximum rate probably was reached about 7:30 and continued to 9:30 or 10 o'clock. In these 2 to 2½ hours, over 600 pounds of high explosive were fired at the rate of 2 to 2½ pounds per minute. As the firing was going on in four sections of the mine simultaneously, a very large quantity of dust was thrown into the air-current at many points. The open condition of the workings combined with the large-volumed air-current permitted the dust stirred up by the rapid shot firing to be disseminated all over the mines.

In order to keep down the dust, water lines were laid throughout the mine, except in the first and second west B entries, which had but recently been reopened after abandonment for some months. At various points on the intake were placed a total of 12 sprays, but these were not always in operation. A water car was also in use. A man known as a sprinkler was employed to wash down the ribs and roof by a hose attached to the main water lines by connections at convenient distances apart. At the inquest this man testified that he washed the places as often as necessary and usually was able to make his rounds once every 4 days. The rooms were not watered. However, as the mine made considerable water, the entries were generally wet and in some places the floor was covered with standing water. The fifth south entry for a large portion of its length is driven through rock shot down to bring up the grade and is naturally wet. The entries in the C block are also naturally wet and the same may be said of the last 500 to 750 feet of all the eight west B entries. The humidity of the return air was determined regularly and ranged from 85 to 95, and even more, per cent.

On the night of the accident, in addition to the eight shot firers and their boss, there were in the mine eight entry men employed two each in the fourth, fifth, seventh, and eighth west C entries, a total of 17 men, of whom two of the shot firers escaped.

The shot firing crew met at the powder house at the customary hour, 5:45 P. M., and there received 648 pounds of high explosive. Of this 166 pounds were two permissibles, which were being tried out, and the remainder consisted of dynamite. After the accident a sack containing one-half the supply of permissible powder was found untouched and the records showed that the remainder of this kind of powder had, with the highest degree of probability, been used up shortly before the explosion. Further, investigation has shown that at the time of the explosion 183 holes had been fired, consuming at the usual rate of 1.4 pounds per hole, 256.2 pounds of dynamite, and this had all been fired in about 2 hours, or at the rate of 2.13 pounds per minute.

At about 8:55 P. M. the two shot firers, who had been accompanied by the boss shot firer, prepared the holes in the twenty-first room on the first west B entry. What happened next is largely conjecture. It would seem from all the evidence at hand that these men, in violation of the rules, carried a sack of powder to a point about 20 feet from the face of this room. How much powder was in the sack is uncertain, but one, well qualified, testified at the inquest it could not have contained less than 20 pounds, and may have held as much as 50 or more pounds of high explosive. It further appears that after the holes were ready the head and boss shot firer started to leave the room, one of them picking up the wooden tamping bar and both overlooking the sack of powder which was in the center of the track. The assistant shot firer, presuming that the other two had taken the powder as was the custom, lit the fuses and went through the breakthrough into No. 22 room, down it to the entry, and was with the others in the cross-cut between the twenty-third and twenty-fourth rooms when the explosion took place. The location of the men at the time is determined by the finding of the tamping bar in the cross-cut mentioned.

Just why the dynamite exploded is uncertain. About 20 feet back from the face, and toward which is directly pointing a shot which blew out both at the back end and the mouth, is a hole in the center of the track of some 6 square feet in area and something over 2 feet in depth in the solid floor. All the timber in the room was blown back from the face and some of it lodged in the mouth of the room and some was thrown out into the entry. The ties were ground to powder and the rails twisted and bent. Sections of the rails were torn out from the web and flanges and thrown considerable distances, and all the evidence points to this having been the focus of an explosion of extreme violence. There were other foci of violence *F*, as shown on the map, in the twentieth room on the fourth west B entry, at the mouth of the eighth room on the same entry, and at the mouth of the tenth room on the fifth west B entry. Aside from the fact that none of these places shows even approximately the violence displayed in the twenty-first room on the first west B entry, there is not known to have been any powder near them or men working in their vicinity. They must be abandoned as points of origin in favor of the one named at the outset. At the origin of the explosion the hole named may have been dirty and the flame from it may have ignited the dynamite, or its detonation may have been caused by a lump of coal thrown against it at high velocity, or possibly by a piece of roof falling thereupon.

The limits within which evidences of heat, as determined by coking action, and of force, as determined either by the scouring of the ribs or by the destruction and displacement of timbers, brattices, mine cars, and the like, are shown by a dotted line surrounding the area so affected.

Evidences of heat and destructive action are naturally not uniformly distributed throughout this area. The centers of force are shown on the map marked with the letter *F*, and with a single exception are where the explosive wave passed from a larger to a much smaller area of workings, thus gathering in intensity by reason of compression. This exception was met in the twentieth room on the fourth west B entry. At this point forces apparently met from opposite directions and, the room being wide, set up a whirling or rotary motion sufficiently violent to throw out the gob some 4 feet deep in a circle 15 to 20 feet in diameter.

At the mouth of the eighth room on the fourth west B entry, and also at that of the tenth room on the fifth west B entry, mine cars were completely destroyed, the wheels being torn off, axles bent, and frame irons curved out of shape. At the undercast at the fourth south and seventh west entries, where was placed a large electric pump, the violence was severe. The pump house of 2-inch lumber was blown in and down into the sump. The pump was badly damaged, the pipe connections,

plunger shaft, and outside gear being broken. The 3-inch floor and a heavy wooden brattice were blown down into the undercast and two 6"×6" supports to the pump were broken. The undercast being built of heavy reinforced concrete was cracked slightly and showed some leakage where it intersected the coal. The rails over the undercast were raised about 4 inches.

At the foot of the slope the destruction was more complete than elsewhere. The timbers at and near the mouth were thrown out and some broken in two and hurled outside 100 feet or more. Cars on the slope were smashed and thrown outside and the loaded trip at the foot was badly shattered. The wooden floor of the chain haul was ripped out and a 12"×14" Oregon pine timber supporting the sheaves at the bottom was broken in two. Two double steel doors set in concrete in breakthroughs between the main slope and the return airway were blown out toward the fan. The concrete was entirely blown out and the doors, badly bent and twisted, were carried 75 feet.

At the fan no damage was done. The explosion doors were blown open and immediately shut automatically and the light roof on the top of the air-shaft was lifted off and at once fell back into place.

Beyond the limits marked on the map there were no evidences of violence other than the blowing open, without damage, of a door or two. Aside from the two mentioned at the foot of the slope, the few brattices in the mine, which were of concrete were unharmed.

The coking action was as variable in intensity as was the force. On the map the zones of greatest heat unless plainly marked are indicated by the letter *C*. In these zones coke up to 2 inches and more in thickness was very general. On the third and fourth south entries between the second west and third west entries was one extensive heat zone. Here, in addition to coke 2 and even 3 inches deep on the caps, the posts were found to be scorched and the solid rib was coked to a depth of ½ inch in places.

The most extensive area of coking action was found in the rooms on the fourth west B entry. In some of the rooms in this section coke was found on the ribs from roof to floor and from mouth to face, as well as on the roof and floor, and on the timbers, and in one instance was nearly 6 inches thick. In some of these rooms there was an additional deposit of carbon as lampblack in long festoons or whiskers upon the coke, indicating that the oxygen in these rooms had been completely consumed.

The course of the explosion, owing to the open and connected character of the workings was difficult to trace, but it is believed that its direction, as shown by the arrows on the map, has been fairly well determined. It will be noted that in some instances the wave came through some rooms out an entry to be met by an entering wave from the fourth south. Where these waves met there was generally a neutralization of force or else a whirling action through the cross-cuts. In any case the advance of the wave may be plainly traced from the twenty-first room on the first west B entry to daylight.

The effects of the heat wave displayed the usual vagaries. The mule hitched to the powder car which was standing near the mouth of the first west B entry was burned, as well as was a sack containing dynamite in the car itself, but no explosion occurred. In one room a coil of fuse would be found burned and in the adjoining room under apparently identical conditions the fuse would be untouched.

Strictly speaking, the explosion at Cokedale was rather an inflammation or burning of coal dust ignited by an explosion of dynamite rather than a true explosion in the accepted meaning of the latter word. There was most intense heat and but little damage throughout the workings. The writer is forced to the conclusion that the wide area affected by the explosion, aside from the dust generally present, was due to the large amount of oxygen available for burning whatever dust was present and the universal connection of the workings.

Without any exception whatsoever, where the heat action ceased, the stoppage was due to want of fuel in entries, which were not only damp but actually wet and not uncommonly shoe-top deep with mud. In one instance the flame leaped over a wet zone about 150 feet wide but was stopped shortly beyond. In some places the presence of rock in the track dust helped to stop the spread of the inflammation, and in others the same end was accomplished by rock in the ribs and roof where the latter had been shot down in a local swamp.

On the map are given certain combinations of letters and figures as *2A*, *E*, and *F*, *2D*, etc. The letters indicate the place where a man or men were working at the time of the accident; the figures, the number in the place in question. A letter without affixed number means that but one man was working there or that, if more than one was employed in the place, the bodies were not found together. It will be noted that two men were working in the seventh and eighth west C entries, denoted by *2A* and *2B*, respectively. After the explosion these men started to run out and were a trifle over 1,800 feet from the face when overcome by gas. The four men in the fourth and fifth west C entries (*2C* and *2D*) were found 1,300 feet away on the fourth west B. The two shot firers (*E* and *F*) who were in the first west C entry were able to go over 1,900 feet, their bodies being found on the first west B entry near its intersection with the fourth south entry, with those of the two shot firers and the boss shot firer (*G*, *H*, and *I*) who were in the breakthrough between the twenty-third and twenty-fourth room on the same entry at the time of the explosion. The two shot firers (*J* and *K*) were working in the newly started twenty-fifth room on the fourth west B entry in the hottest part of the coking zone, and were only able to go 75 to 100 feet before being overcome with the gas.

The evidence at the inquest showed, although no analyses of the blood were made, that all the men died from CO poisoning. Their bodies were flaccid and faces peaceful with none of the signs of strangulation apparent in those dying by means of CO_2.

Of the 15 miners and shot firers who succumbed to the effects of gas, the lives of 10, those working in the C block, might have been saved. It will be noted that the explosion did not come within 500 feet of the C block at any point. Also the two doors on the fifth south entry used to force the air up the fourth and fifth west and first and second west entries, respectively, were blown open. The poisonous gases, therefore, did not enter the C block at all, and had the men remained in their working places and bratticed themselves off (there was an abundance of brattice cloth and lumber at several places on the fifth south) they could have for all practical purposes remained in absolute safety indefinitely.

The lives of the three men on the first west B and of the two on the fourth west B entry (*G*, *H*, *I*, and *J*, *K*) could not have been saved, as they were either inby a coking zone or immediately in it.

The two survivors were at the time of the explosion near the intersection of the sixth west B and second south entries at the point *L*, *M*, on their way to shoot a few pillars in the A block. Both testified that they first felt a rush of cool air in the face which blew out their lights and which was instantly followed by a hot blast from inside which knocked them down The hot air had a distinct smell of burning coal. This preliminary inrush of cold air is interesting and is analagous to the experience of two men near the outlet of the Lick Branch, W. Va., mine, at the time of the second explosion there, to which my attention has been called by Mr. John Verner, of Chariton, Iowa.

The rescue cars of the Colorado Fuel and Iron Co., stationed at Trinidad, and that of the Victor American Fuel Co., from Hastings, were on the ground shortly after midnight and their large force of trained men and excellent equipment rendered invaluable service, as the rescue crew of the mine itself, being

composed solely of shot firers, were either dead or, as in the case of the two survivors, incapacitated for further exertion.

As stated before, but little damage was done to the mine and the temporary stopping of the destroyed brattices at the foot of the slope, of the door at the eighth west B, etc., soon restored the normal circulation. The bodies were all discovered in a few hours except two, which were not found and brought out until Saturday noon.

An extremely unfortunate feature of this accident was the death of E. A. Sutton, assistant superintendent at Cokedale, and of Robert Meeks, tracklayer at Starkville, who ventured beyond the rescue station at the fourth south and sixth west B entries, and who were overcome by *CO* gas in the fourth west B entry at a point about 300 feet in and marked by the letters *M S* on the map.

It remains then to consider the two theories of dust origin as commented upon at the outset in this article. Was the dust which propagated this explosion that which was made during the few minutes prior to the accident by the abnormally rapid shooting of friable coal, or was it that which had accumulated in the workings as the result of days or weeks of operation?

Draw a line between the twenty-first room on the first B entry and the twenty-fifth room on the fourth west B entry. Whatever dust was created by shot firing on the west side of this line did not figure in the explosion, because the air-current was drawing it away from the initial point, and also the explosion did not travel inby from its point of origin. Hence, only the dust created by shot firing on the outby, or east, side of this line could have served as a propagating agent. But there were no shots fired on this outby, or east, side the night in question. Had some been fired in Japan the conclusion would not be affected for the inflammation did not enter Japan for lack of fuel. Hence we must dismiss the idea that the explosion of dynamite in the twenty-first room on the first west B entry can be connected with the next nearest place of shot firing, the twenty-fifth room on the fourth west B entry, by means of newly created dust.

By way of the route of the explosion it is a full half mile between the above points, and in this distance there is one zone of most intense heat and two smaller ones. The first and second west B entries were undoubtedly dry and dusty, being without water lines and were but newly opened up. It is probable that the third and fourth south had not been watered for 3 or 4 days, the sprinkler being then about to reach them on his rounds. It is an easy matter to connect up these points on the supposition of standing dust and impossible to do so on the theory of newly created dust.

Similarly, it does not seem that the intense heat and enormous deposits of coke in the coking zone on the fourth west B entry which covers an area of over 4 acres were due to any thing but standing dust. It is impossible to say how long it would have taken at Cokedale to clear the atmosphere of dust after a shot was fired. The slowly moving air-current was favorable to the speedy deposition of the dust and 10 minutes after firing a shot may have seen it all deposited. As the section under consideration was but one of four shot-firing zones, the rate of fire therein would be one-fourth of the rate for the entire mine. That is, if the average for the mine demanded the firing of 2 pounds of dynamite a minute, this section calls for the explosion of 2 pounds in 4 minutes, or a total of 5 pounds in our assumed 10 minutes. To any one who has seen the deposits of coke in this zone, some of them covering an area of nearly 500 square feet, and varying from ½ to 1 inch, and rising to 4 inches in places in thickness, combined with the festoons of soot in some of the rooms, the view that this heat action was due to the limited amount of dust possible through the explosion of but 5 pounds of dynamite, is untenable. Nothing but standing dust can account for the phenomena.

And finally in this connection, had there been any large amount of dust in suspension in the air in this section it would have, by means of the air-current, been drawn into the C block workings. That this was not the case is proved by the fact that the explosion on all the west B entries stopped within 600 feet of this block. Had the C block been dusty it would have inflamed.

This theory has been touched upon at length, as it is a most important one, as pointed out in this journal when commenting upon an editorial in the *Mining Journal*, of London, England, treating of the Hulton colliery disaster. Intensity of working, abnormally rapid shot firing and the like, unquestionably favor the propagation of explosions by means of dust created through the rapidity of production. But this was not the case at Cokedale.

It does not seem that the Cokedale accident teaches any new lessons, but it does serve to emphasize some old ones. It shows that open and connected workings combined with an air-current of large volume favor the propagation by means of dust of an explosion otherwise started, by disseminating the agent of this propagation over a large extent of workings and by furnishing a large volume of oxygen (air) for its combustion. It shows that, by reason of the above, to limit the spread of an explosion, the workings should be, as far as possible, not connected, and should be ventilated by separate splits with only as much air as the health of the men demands. It shows that material damage to the mine is done where the wave passes from a cross-section of larger to one of a smaller area by reason of the compression thus set up. It shows that zones of intense heat action are not necessarily connected with zones of violence. It shows that, in the presence of intense heat action, very wet zones up to 150 feet in length may be crossed by the inflammation, and it shows that very wet zones, particularly if in rock or where the floor dust is heavily impregnated with rock, and of sufficient length, will invariably stop the advance of a wave of inflammation.

This accident clearly demonstrates that rescue crews should never consist of less than four men each; that they should be carefully trained, be drawn from men of diversified lines of work, and be equipped with the latest and best apparatus.

It will be admitted that if oxygen (air) be absolutely excluded from a mine there can be no inflammation; if there be no dust, there can be no inflammation regardless of the amount of oxygen (air), and that, regardless of the amount of oxygen (air) and dust present, if this dust be in the condition of watery mud, if the mine be absolutely saturated with water, there can likewise be no inflammation.

When the relationship between these three, oxygen (air), dust, and moisture (water), which must exist in order to render impossible the propagation by means of dust of an explosion otherwise started, has been determined, accidents such as those described herein will be impossible.

LIBRARY OF THE ENGINEERING SOCIETIES

Attention is called to the facilities offered by the Library of the Engineering Societies, at 29 West Thirty-ninth Street, New York City. The library, formed from the combined libraries of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, and the American Institute of Mining Engineers, contains over 40,000 volumes on engineering subjects. It is open for reference to the general public, without charge, every day and evening, except Sundays.

Those residing in New York City and vicinity are invited to utilize the library in their researches on technological subjects. The library is prepared to furnish references on engineering subjects to persons at a distance, and also furnish transcripts, translations, and photographic reproductions of diagrams and maps. For such work, if extensive, a moderate charge is made. Correspondence is welcomed; telegraphic and telephonic inquiries will receive especial attention.

PUMPING AND SIPHONING HOT WATER

Written for Mines and Minerals, by J. T. Beard

A common difficulty experienced in mining and steam-engineering practice is that of handling hot water by means of pumps and siphons. In the drainage of mines it frequently happens that the exhaust steam of the pumps or underground haulage engines is conducted into the sump where its condensation raises the temperature of the mine water in the sump to a degree that seriously interferes with the action of the pump in raising this water to the surface. Under these conditions a pump or a siphon may be rendered utterly helpless to draw the water from the sump. In many cases, judging from the frequent inquiries made, the cause of the trouble is not known to the pump runner or the mine foreman in charge, who may spend several hours in a fruitless endeavor to locate and remedy the evil. The difficulty and annoyance is greatly increased at

Difficulties and Their Causes. Effect of Temperature of Water and Elevation Above Sea Level

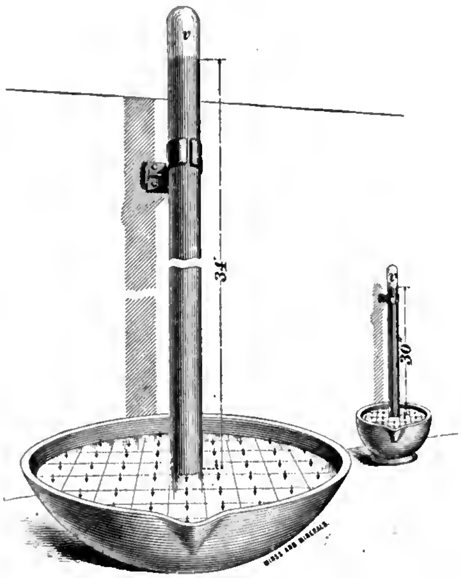

Fig. 1

high altitudes, and is greater as the temperature of the water increases.

In order to clearly understand the difficulty and comprehend its cause, it is necessary to call to mind that in the case of both the pump and the siphon, it is the pressure of the atmosphere acting on the surface of the water in the sump, or supply basin, that forces this water to enter and rise in the suction pipe a height dependent on two factors: (1) the pressure of the atmosphere or barometric pressure; (2) the degree of vacuum within the pipe. A vacuum gauge on the pump or at the crown of a siphon will show the net result or the lifting power in such case, and determine the height of suction.

Turning now from the pump and the siphon, consider, for a moment, the principle of the mercurial barometer. The atmospheric pressure acting on the surface of the liquid in the basin (Fig. 1) supports a column of liquid of such height that its weight is equal to the pressure that sustains it, area for area, as long as a perfect vacuum exists in the tube, at v, above the column, so that there is no pressure at that point. For example, the normal atmospheric pressure, at sea level, is 14.7 pounds per square inch; and since 1 cubic inch of mercury weighs .49 pound, the height of mercury column the pressure of the atmosphere will support at sea level, or the normal barometric height at sea level, is $14.7 \div .49 = 30$ inches. In like manner, since 1 cubic inch of water, at say 62° F. (normal), weighs .03608 pound, the height of water column the pressure of the atmosphere will support, at sea level (temperature of water 62° F.), assuming a perfect vacuum, is $14.7 \div (.03608 \times 12) = 33.95$, or practically 34 feet.

In the case of water, however, there cannot be a perfect vacuum above the column of liquid since this space v (Fig. 1) is always saturated with water vapor, the vaporization taking place instantly, to the point of saturation. This water vapor exerts a pressure that increases rapidly with the temperature and reduces the height of the water column supported by the atmosphere. At 62° F. (normal) the tension of water vapor is .2731 pound per square inch, which is equivalent to .5561 inch of mercury column, or .63 foot of water column. This is no inconsiderable reduction in the suction lift of a pump or siphon even at normal temperature and sea level. At higher temperatures of the water and at greater altitudes the reduction may and often does incapacitate the pump or the siphon, as the case may be. Thus, at sea level, the theoretical water column (34 feet), supported by the atmosphere under normal conditions, is reduced by the vaporization of the water to 33.3 feet when the temperature of the water is 60° F.; 30.3 feet at a temperature of 120° F., and to 17.1 feet if the water is heated to 180° F., as is often the case with feedwater before it is pumped into the boiler.

The foregoing refers only to the static water column supported by the atmosphere, and shows the effect of the vaporization of the water in the reduction of the height of water column supported. In the operation of a pump or siphon there are other losses that greatly reduce the vertical height the atmospheric pressure will force the water in the suction pipe, or what is called the suction head. Briefly summarized these losses arise from the following causes: leakage of valves and packings, and slippage of water past the piston; air absorbed or entrapped in the water, and which escapes under the reduced pressure of the vacuous space above the suction column; friction of the water in the suction pipe and resistance of valves. These losses vary greatly according to the character of the apparatus and the conditions that create them. In common practice such losses may be assumed as averaging 25 per cent. of the theoretical head, after making due allowance for the reduction of the suction head by reason of the vaporization of the water.

Table 1. Safe Suction Head for Pumps at Different Elevations and Various Temperatures of Water

Elevation Above Sea Level Feet	Atmospheric Pressure Pounds Per Square Inch	Barometric Pressure Inches Mercury	Temperature of Water Raised Degrees Fahrenheit				
			60	90	120	150	180
			Safe Suction Head for Pump (Feet)				
10,000	10.107	20.582	17.0	16.4	14.7	11.3	4.7
5,000	12.224	24.890	20.5	19.9	18.2	14.8	8.2
4,000	12.689	25.837	21.5	20.9	19.2	15.8	9.2
3,000	13.169	26.813	22.4	21.8	20.2	16.8	10.2
2,000	13.665	27.824	23.2	22.6	21.0	17.6	11.0
1,000	14.174	28.861	24.1	23.5	21.9	18.5	11.9
Sea level	14.696	29.925	25.0	24.4	22.8	19.4	12.8
Tension of water vapor at various temperatures..........		Lbs. per Sq. In.	.255	.693	1.683	3.706	7.500
		Inches mercury	.518	1.410	3.427	7.547	15.272

Suppose, for example, at an elevation of 2,000 feet above sea level, a pump is to be installed to pump water having a temperature that may reach 120° F., and it is required to ascertain the height it would be safe to set the pump above the low-water mark in the sump or basin. The normal atmospheric pressure at this elevation is 13.665 pounds per square inch. Deducting from this the tension of water vapor at 120° F. gives for the effective pressure that acts to force the water up the suction pipe to the pump $13.665 - 1.683 = 11.982$ pounds per

square inch. A cubic inch of water at 120° F. weighs .0357 pound; and this pressure therefore corresponds to a water column of $11.982 \div (.0357 \times 12) = 27.9$ feet. Now, deducting 25 per cent. to allow for frictional and other losses, the safe suction head, in this case, is $27.9(1 - .25) = 21$ feet.

On this basis Table 1 has been prepared and is offered here as suggestive of the variation in the safe suction head

Fig. 1. Three-Piece Steel Set Used by Susquehanna Coal Co.

for pumps and siphons, at different elevations above sea level, and for various temperatures of the water raised.

The values given for the safe suction head in the above table refer to pumps and siphons where the suction pipe is vertical, or nearly so. When the suction pipe is much inclined, as is sometimes the case in pumps, but more often and quite generally the case in siphons, the length of the pipe and consequently its frictional resistance is increased and varies inversely as the sine of the angle of inclination of the pipe, or the angle the pipe makes with the horizontal plane. The valve resistances, leakage, or slippage, and other losses are not changed.

To ascertain how the inclination of the pipe affects the suction head it may be assumed that of the 25 per cent. of losses in vertical suction, 10 per cent. is due to pipe friction. If this be approximately the case under ordinary conditions of installation, the suction-head values given in the table, and which apply only to practically vertical pipes, must be modified by multiplying by the expression $1 - \frac{10}{75}\left(\frac{1}{\sin a - 1}\right)$, where a is the angle of inclination of the pipe. The limiting angle of inclination is found by making this expression equal to zero, when $a = 6° 45'$, in which case the length of the suction pipe is 8.5 times the vertical lift. For example, assuming the above conditions, the suction pipe of a siphon, at sea level, and using water at 60° F., would cease to deliver any water at the crown when the length of the suction pipe was $8.5 \times 25 =$ say, 212 feet. The water would run slower and slower as this limit was more nearly approached; and it would be necessary to reduce the size of the long leg (discharge pipe), or to throttle the discharge, to prevent the siphon from emptying itself.

The values given in the table for the safe suction head under different conditions, are only intended to be suggestive of practice under ordinary conditions. A good pump will often exceed the suction head given here by 1 or 2 feet; or a poor pump may not stand up to the values given. Bends and elbows in the suction pipe greatly reduce the head The principle of suction, however, in its application to pumping and siphoning, is clearly shown; and the effect of elevation above sea level and raising the temperature of the water is made plain. The aim of the writer has been to show, in a practical manner, the limitations of these operations, and to give sufficient data for the calculation of the safe suction head in any given case.

INTERLOCKING STEEL MINE SUPPORTS

Written for Mines and Minerals

In an interesting article on "Steel Supports in Coal Mines,"* R. B. Woodworth, engineer for the Carnegie Steel Co., says: "For the legs and props, where loads have to be carried in compression, the highly economical integral section was not rolled in the United States 4 years ago. The **H** beam, which is the closest practical approximation in the form of a rolled shape to the section of the largest compressive resistance in proportion to its weight, has been found the section best fitted for use both as single props and for legs of the three-piece gangway support, and its introduction can be said to mark an era in the history of American mine timbering as it did when introduced in England by the Darlington Iron and Steel Co., in 1885. The use of this section has been extended to include the framing of mine shafts. When used for wall plates of a mine shaft the **H** beam has the advantage of a large bearing surface as compared with beams or channels of the same depth, and for buntons and compartment separators the advantage of a large compressive strength combined with a comparatively high moment of resistance against bending."

When R. Van A. Norris introduced the three-piece set in the Susquehanna Coal Co.'s mines at Nanticoke, Pa., he made use of channels for legs and **I** beams for collars. The collar rested on a pin that separated the two steel channels that formed the leg. This is shown in Fig. 1. Later on, 85 sets of the three-piece supports shown in Fig. 2 were introduced in the Allport Coal Co.'s mine at Barnesboro, Pa. In the latter sets the collars are riveted to the legs. Dr. Wesley Waite got the notion that he could improve on this kind of mine support and invented the knock-down interlocking three-piece set, shown in Fig. 3 knocked down and in Fig. 4 set up. As shown in Fig. 3, the collar a and the legs b of **H**-shaped iron or steel are slotted in such a manner that the legs will interlock with the collar.

The slots made in both ends of the collar do not extend quite to the web, in order that it may not be weakened and

Fig. 2. Steel Gangway Supports, Allport Coal Co., Barnesboro, Pa.

further that some play may be allowed between the members so that a natural adjustment may occur when pressure comes on the set. The legs are slotted so as to remove the web and permit the web of the collar to rest on the flange of the leg. If desired, the legs and collar can be matched on the floor and raised as a whole into place, or the legs can be stood and the collar placed on them. In Fig. 4 the legs are given a batter, but they can be stood upright, in which latter case a key keeps

* Mines and Minerals, Vol. XXXI, No. 7, page 387.

the legs from lateral motion and so vertical. The slots in the collar are made to conform with the angle at which the legs are to stand.

In the Waite patented interlocking mine-support system, the legs and collar act as an integral piece of steel to the section and impossible of shearing at any angle. To destroy the jointing the whole section must be crushed. An advantage claimed for this construction, in addition to the ease with which it may be adjusted to conform with requirements in setting up, is that each set is so adjusted that it will take up strain throughout many sections on account of the loose joints. Where steel is riveted this strain comes directly on the parts affected and it cannot yield. In wooden supports there is a certain yielding which is advantageous. The two pieces of iron under the collar in Fig. 3 are hooks for spacing the bents and keeping them from moving out of place when pressure comes on the sets unevenly. Where the legs are battered inwards, as in Fig. 4, downward pressure tends to tighten the joints; or if there is lateral pressure on either or both sides of the set both the legs and collar resist it as a unit on account of the interlocking.

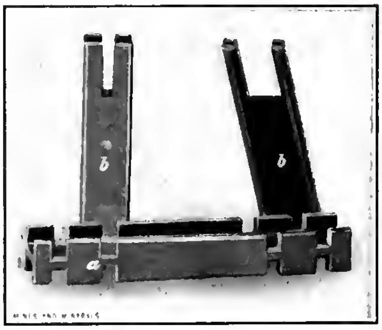

Fig. 3. Knockdown Three Piece Steel Mine Support

"SHEELITE" IN NOVA SCOTIA

An interesting event is the recent discovery of "sheelite" in Halifax County, Nova Scotia. Sheelite is one of the minerals containing tungsten. It is of no known use in itself, excepting as an ore from which tungsten may be extracted. The mineral is chemically a tungstate of calcium. As an ingredient in the chemical side of steel making it is quite important. At present the world's annual output, coming mostly from Sweden, is placed at 4,000 tons. If present indications are correct, the recent discovery in Nova Scotia will not only yield sufficient for the steel plants in the Province, but will have an effect on the markets of the world. The ore is reported to yield 60 per cent. of tungsten acid to the ton of sheelite. At present 25 men are at work on the preliminary experiments. It is believed that Mr. Hiram Donkin, Deputy Commissioner of Mines, Halifax, Nova Scotia, will give interested parties all reasonable information.—*From Consul John E. Kehl, Sydney.*

REPORT OF COAL MINE INSPECTOR OF COLORADO

Written for Mines and Minerals, by Geo. F. Duck

The recently issued report of James Dalrymple, State Inspector of Coal Mines for Colorado, for the years 1909 and 1910, covers a most interesting period in the history of coal mining in that state; a period during which the fatalities reached the enormous total of 21.6 per 1,000 employes. So far as our records show, but twice in the history of coal mining in the United States has this rate been exceeded: In Utah in 1900, when it was 138.96 per 1,000, and in Tennessee in 1902, when it was 25.80 per 1,000. In British Columbia in 1901 the rate was 25.67, and in 1902, 34.65, and in Nova Scotia in 1890, 25.17. The abnormally high death rate in Colorado during 1910 is due to four major accidents which cost 220 lives: Those at Primero on January 31, 76; Starkville on October 8, 55; Delagua on November 8, 79; and at Leyden on December 14, 10. These four accidents alone caused a death rate of 14.89 per 1,000. The difference between the total fatality rate for the state, 21.6 per 1,000, and that due to these four accidents, 14.89, is 6.71, or essentially the same as the rate of 6.76 per 1,000 for the year 1909, when there was, strictly speaking, no major accident, the largest being that at Toller on July 6, when nine lives were lost.

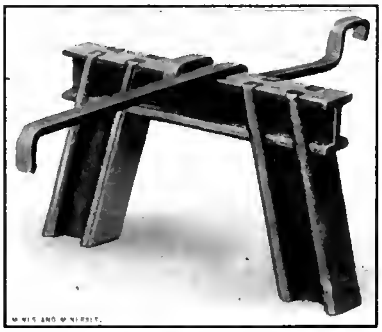

Fig. 4. Steel Mine Support Assembled

In addition to very interesting reports on the Toller, Primero, and Delagua accidents, by John D. Jones, the recently retired Chief Inspector, there are others of moment by James Dalrymple, the present chief, on the Leyden fire, and by Frank N. Oberding, deputy inspector, on the accident at Starkville. There is also a very timely article by Prof. John B. Ekeley, of the University of Colorado, Boulder, on the coal dusts and mine gases of the state, with analyses of numerous samples from various mines.

The following interesting statistics are taken verbatim from the report:

General Statistics

	1909	1910
Number of mines in operation	167.00	155.00
Number of new mines opened up	15.00	12.00
Tons of lignite coal produced	2,173,877.00	1,654,955.00
Tons of semibituminous coal produced	855,762.00	1,014,588.00
Tons of bituminous coal produced	7,613,332.00	9,284,758.00
Tons of anthracite coal produced	59,519.00	80,586.00
Tons of unclassified coal produced, estimated	70,000.00	70,000.00
Total number of tons of coal produced	10,772,490.00	12,104,887.00
Increase in number of tons as compared with 1909		1,332,397.00
Tons of coal mined by hand	9,033,057.00	10,563,651.00
Tons of coal mined by machinery	1,739,433.00	1,541,236.00
Total number of mining machines used	208.00	222.00
Total number of tons of coke produced	1,076,593.00	1,190,901.00
Total number of coke ovens	3,240.00	3,164.00
Number of employes in and about the mines	13,156.00	14,768.00
Number of employes at the coke ovens	1,089.00	1,090.00
Number of non-fatal accidents	116.00	146.00
Number of fatal accidents in the mines	89.00	319 00
Tons of coal mined for each life lost	121,039.10	37,946.30
Tons of coal mined for each non-fatal accident	92,886.30	82,910.40
Number of employes for each life lost	147.80	46.20
Number of killed per thousand employed	6.76	21.60
Number of employes for each non-fatal accident	113.40	101.20

Accident Statistics

	1909	1910	1909	1910
Total number of accidents	79	96		
Total number of men killed	89	319		
Total number of men injured	116	146		
Serious injuries			79	115
Minor injuries			37	31
Total number of wives made widows	50	163		
Number of children left fatherless	71	303		
Causes	Killed		Injured	
Gas explosions	10		13	9
Dust explosions (including mixtures of dust and gas)	3	210		
Falls of roof, coal, rock, and draw slate	63	73	70	79
Powder explosions			2	2
Crushed by trip cars	7	18	25	28
Shaft accidents	2	1		2
Miscellaneous	2	3	6	26
Electrocuted	1			
Suffocated	1	14		
Total	89	319	116	146

BRITISH COAL MINING NOTES

Written for Mines and Minerals

Indian Coal Mining Methods.—In the principal coal fields of India the customary method of coal working is pillar and stall, or bord and pillar. Referring specially to the mines in Bengal in the last annual report issued, Mr. J. R. R. Wilson, acting as chief inspector, says that from the mouth of the incline, or the limits of the shaft pillar, the area is gradually cut up into pillars, the output depending upon the amount of coal extracted in the galleries. This operation continues until the boundary of the royalty is reached, and then the work of extracting the pillars is commenced.

Sometimes it happens that the demand for coal is so large that an effort is made to take out the larger percentage of coal in the seam by means of the galleries, and the pillars that are then left are barely of sufficient strength to resist the weight of superincumbent strata; consequently, when the boundary of the property is reached the mine has to be abandoned and the coal in the pillars is lost. Further than this, gallery driving yields a far greater percentage of small coal than pillar cutting, the work is more arduous, the cost per ton is higher, and the output per person employed is considerably less, so that for long after the mine has started it is worked at the greatest disadvantage from every point of view.

It is further stated that several seams in India are liable to spontaneous combustion, and the danger from fire is always present after pillar cutting or goafing has started. The small pillars of coal left behind as temporary supports are crushed into heaps of dust by the weight of the roof, and spontaneous combustion invariably follows. When this happens it is impossible to get near to the heated coal to shovel it out, or to quench it with water, on account of the fallen stone in the goaf, and the only effective remedy is to isolate the area where the fire occurs from the rest of the workings. With a network of galleries opening out of the goaf on all sides this is often a gigantic undertaking, for every outlet will have to be hermetically sealed by walls to prevent the spread of the fire. Unless a fire is checked or extinguished immediately after its discovery in the goaf the chances of successfully coping with it are very small.

The assumption of Mr. Wilson is that the adoption of any system that would facilitate the separation of parts of the mine from the rest and at the same time obviate the aforementioned difficulties must be of immense practical value. It is recalled that in the early days of active coal mining in England these difficulties presented themselves, and in 1809 Mr. Buddley, a famous North of England colliery manager, overcame them to a very great extent by the introduction of the panel system, a system which effectually separated adjoining districts of the mine by leaving solid ribs of coal of varying thicknesses between them. The workings are laid out in districts or panels in this system of a size to suit the local condition, and when one panel is cut up into pillars these are immediately extracted. Only three or four roads are made into each panel for the purposes of ventilation and haulage, so that in the event of a fire or a sudden inrush of water the panel could be quickly dammed off. Mr. Wilson concludes that the introduction of paneling into Indian methods of mining coal cannot fail to be beneficial in every way. A minimum of risk in case of fire or sudden inrushes of water, the production of better coal, and a quick return on the capital expended, are amongst the chief advantages to be derived.

Stone Dust Zones.—The Official Record of the British Coal Dust Experiments, issued on behalf of the Mining Association of Great Britain, is an important and a valuable document. In carrying out the experiments at Altofts, in Yorkshire, attention was given to details, and more than 800 coal owners, colliery officials, inspectors of mines, and scientists from all parts of the United Kingdom, from India, and South Africa, and from France, Germany, and America, witnessed demonstrations. So much that is general has been conveyed to the rank and file of mines regarding the value of stone dust as a means of preventing the ignition of coal dust, that an excerpt may be acceptable, giving the suggestions of the committee for distributing stone dust in the pits.

They say the effect of stone dust as a "zone" in the path of a coal-dust explosion would seem to lie in its power of offering resistance to the projection of the flame of the explosion. That is to say, its action is mainly mechanical. The cloud of incombustible particles in the air immediately in front of the explosion presents a denser atmosphere, offering greater resistance and prevents the flame of the explosion from penetrating so far as it would in dust-free air. At the same time it diminishes the danger of the flame of the explosion spreading through the cloud of unburnt coal dust driven in front, since it mixes with it and in this way raises its ignition point. For stone dust to act in this way, however, it is essential that it must be fine enough to be raised as a cloud in the path of the explosion, and it has yet to be proved whether its action would be sufficiently rapid when dealing with an explosion that has traveled a longer distance and has attained its maximum velocity of propagation. The value of stone dust would appear to lie more in its use as a diluent, thus preventing an ignition, than in any specific action it may have in stopping an explosion that has once started. It would, therefore, seem advisable not to employ zones of any description, whether dustless, watered, or stone dust, in spite of the good results that have been given by the last named when dealing with an explosion that has traveled 275 feet. The better principle would appear to be to treat with stone dust all places where coal dust can accumulate, and in this way guard against the primary ignition of coal dust; for it is a far easier matter to prevent an explosion ever occurring than to stop it after it has traveled some distance, and it is, without doubt, preferable to exclude all possibility of the formation of carbon monoxide by the combustion of even a few hundred pounds of coal dust.

Some Interesting Coal Committee Points.—Dipping into the pages of the Record of the Coal Dust Experiments some highly interesting points may be culled. Amongst other things we are told:

The fact that coal dust, in the complete absence of firedamp, is explosive when raised as a cloud in air and ignited, has, in the opinion of all who have witnessed the experiments, been definitely established.

The development of the flame of the explosion after it issues from the downcast end of the gallery has been studied by means of cinematograph records. The existence of a "pioneering cloud" in front of the explosion has been established, and evidence has been obtained that the true flame of the explosion has a length of from 60 to 80 feet, or possibly less. Lengths of flame outside the gallery of 150 feet and upwards that have been recorded are shown to be due to the subsequent burning of the cloud of coal dust that issues in advance of the flame.

It would appear that the presence of a cloud of incombustible dust in the path of a coal-dust explosion that has traveled 275 feet, checks the continued propagation of the explosion. The experiments in which stone dust has been intimately mixed with coal dust also tend to show that as the percentage of incombustible dust is increased it becomes increasingly difficult either to originate an explosion in the mixture or to cause an explosion to be propagated. It is further shown that the use of stone dust might strike effectually at the root of the danger by controlling one of the factors that are essential for the occurrence of a coal-dust explosion; namely, the inflammability of the dust.

The problem of the mode of propagation of coal-dust explosions is a very complicated one. Of the facts that have been established, the most important are the increase in the pressure developed with increased distance of travel of the explosion, the marked influence of the presence of obstructions in causing

the explosion to be propagated with greater violence, and the possibility of propagating an explosion through a cloud of wood-charcoal dust and air.

Colliery Rescue Brigades.—The British Government, as represented by the Home Office, would appear to be determined upon securing a better system of rescue organization, and a Departmental Committee has reported upon the desirability of the formation of rescue brigades at the collieries, each brigade to consist of not less than five persons employed at the mine, carefully selected for their underground knowledge, coolness, and powers of endurance. The first stipulation is that no person, unless authorized by the manager, or an official appointed for the purpose, shall be allowed to enter a mine after an explosion or the occurrence of a fire for the purpose of engaging in rescue work. Then brigades have to be formed as follows: One brigade where there are less than 250 men employed below; two brigades where the number is between 250 and 500; three between 500 and 800; four above 800. Small mines employing less than 100 miners will be deemed to have complied with the provision upon acquiring the privilege of calling for a brigade from a central rescue station. The order requires that there shall be provided at each mine two sets of portable breathing apparatus for each brigade, capable of enabling the wearer to spend at least an hour in bad air; two electric hand lamps for each brigade; a safety lamp for every member of the brigade. Two or more small birds or mice are to be maintained at every mine for testing for carbon monoxide, and tracings of the workings must be kept up to not more than 3 months previously, the plans to be in suitable form for use by the brigades. At the Central Rescue Stations there must be not less than 15 complete sets of breathing apparatus, properly maintained; 20 electric hand lamps; four sets oxygen reviving apparatus; ambulance boxes, together with antiseptic solution and fresh drinking water; cages of birds and mice; whilst a motor car must be kept in constant readiness.

Maypole and Hulton Disasters.—In the course of an address before the Lancashire branch of the National Association of Colliery Managers, Mr. G. H. Winstanley, lecturer in mining at the Manchester University, recalled that only once in the period of 22 years ended August, 1908, did Lancashire figure in the list of principal colliery explosions. Then the Maypole disaster dispelled any delusion that Lancashire had done with explosions, whilst a few weeks ago, at the Hulton collieries, there occurred a greater explosion than ever previously recorded in the history of the county, and only twice in the history of the world. Mr. Winstanley asked the members to consider the facts. At Maypole, at the time of the explosion, no electricity had been installed. There was no shot firing in the working shift, a good type of safety lamp was in use, excellent airways, and a fan capable of producing more than half a million cubic feet of air per minute. Never had he seen a mine that looked less likely to be the scene of an explosion. As to the Hulton collieries, it was there that the hydraulic wedge, as a substitute for blasting, had its birth. There was little or no shot firing in the true sense of the word, or none in the working shifts. The collieries had earned the reputation of being up to date and replete with all manner of modern improvements. Like Maypole, it had been somewhat of a "show" place. Both places were well conducted and carefully managed. The fact they had to face was that apparently no matter what care might be exercised and what precautions adopted to prevent disaster, they might, any one of them, have a similar experience.

Pointing out that they could not have an explosion without ignition, Mr. Winstanley urged upon managers to "try and fight ignition." Preventive measures might be broadly divided into three groups: (1) Direct treatment of the gas or dust, so as to render it incapable of ignition; (2) the establishment of zones, a sort of forlorn hope to prevent the spread of an explosion already started; (3) precautions to prevent ignition. Water was of all methods the least effective in dealing with the coal dust difficulty. In regard to shot firing, if the strict letter of the law was observed at all times, together with such additional precautions as circumstances might suggest, the risks from this cause might also be looked on as negligible. The match danger was not to be overlooked. They read that within 2 months of that most terrible disaster at Hulton a box of matches was found hidden in a tub at the bottom. He was afraid there was nothing for it but to search the workman before he descended, not with a view to punishment after the offense had been committed, but to prevent the commission of the offense. He urged the importance of managers impressing upon the workmen that they should take a share of responsibility in maintaining the safety in the mine. Bring the workman up in the belief that individual neglect or carelessness might be the cause of a disaster and great loss of life, and that freedom from such calamities was to be attained by a firm determination on the part of every one in the mine, that so far as he is concerned, he will do nothing that might endanger its safety.

PERSONALS

Wm. L. Saunders, B. S., delivered the class day address to the students of the Michigan College of Mines, April 20, 1911. Mr. Saunders is much in demand as a lecturer, because he says something worth while in his speeches.

Prof. Louis D. Huntoon, of the Sheffield Scientific School, Yale University, has resigned the chair of metallurgy at that institution and will open an office in New York City as consulting mining engineer, after the close of the college year.

D. D. Davis, son of W. G. Davis, district superintendent of D., L. & W. coal operations, has been appointed to succeed the late J. E. Evans as superintendent of the United States Bureau of Mines Rescue Car at Wilkes-Barre, Pa.

James Ashworth, manager of Crow's Nest Pass Coal Co., Fernie, B. C., has resigned. He will be succeeded by W. R. Wilson, former general manager of the company. Under Mr. Ashworth's management the Coal Creek and Michel mines have been placed on a sound basis.

J. J. Rutledge, W. S. Rountree, J. D. Weldon, J. W. Key, J. W. Newby, A. R. Brown, William Routenlusch, H. H. Hamilton, G. T. Gambill, Doctor Caraway, and Harry McCrorie, had a narrow escape from death while investigating the cause of the Banner, Ala., mine explosion on April 9. The party were overcome by afterdamp, but were recovered and returned to inspection in a few hours.

Henry R. Cobleigh has resigned as mechanical editor of *The Iron Age*, which position he has held for the last 7 years, to take charge of the advertising and publicity of the International Steam Pump Co., No. 115 Broadway, New York City. He entered upon his new duties May 1.

J. C. Anderson, of Westinghouse, Church, Kerr & Co., Pittsburg, has resigned to take a position as mechanical engineer in the sales department of the Pressed Steel Car Co., New York.

C. T. Van Winkle, former superintendent of the Magna plant, Utah Copper Co., is now consulting engineer for the Duffy estate, of Rochester, N. Y.

W. R. Holbrook, formerly with the Balaklala Consolidated Copper Co., Coram, Cal., is now chief chemist for the Mexican-American Steel and Rail Co., at Guaymas, Mexico.

Daniel Ryan, of Terre Haute, Ind., has been elected president of the Hocking Valley Products Co. the title under which the reorganization, of the Columbus and Hickory Coal and Iron Co. has been effected.

W. J. Jenkins has been elected vice-president and general manager of the Western Coal and Mining Co., of St. Louis, to succeed B. F. Bush. This company operates mines in Illinois, Kansas, Arkansas, and Oklahoma.

SOUTHERN KANSAS COAL DISTRICT

Written for Mines and Minerals, by Lucius L. Wittich

Geology—Extent of Development. Methods Used in Sizing and Cleaning the Coal

More than 65 per cent. of the coal production of Kansas comes from the Southern Kansas district, embracing the counties of Cherokee and Crawford, in Kansas, and Barton County, in Missouri. Comparatively little of the production comes from the latter county, the heaviest producing areas being north and west of the city of Pittsburg, in Crawford County, and near Weir City and Scammon, in Cherokee County. Numerous smaller mining camps are scattered over the Southern Kansas area, among them being Arma, Frontenac, Minden, Mineral, Crowburg, and others. While estimates of the production from this district for 1910 have not been made, it is thought the output will be materially

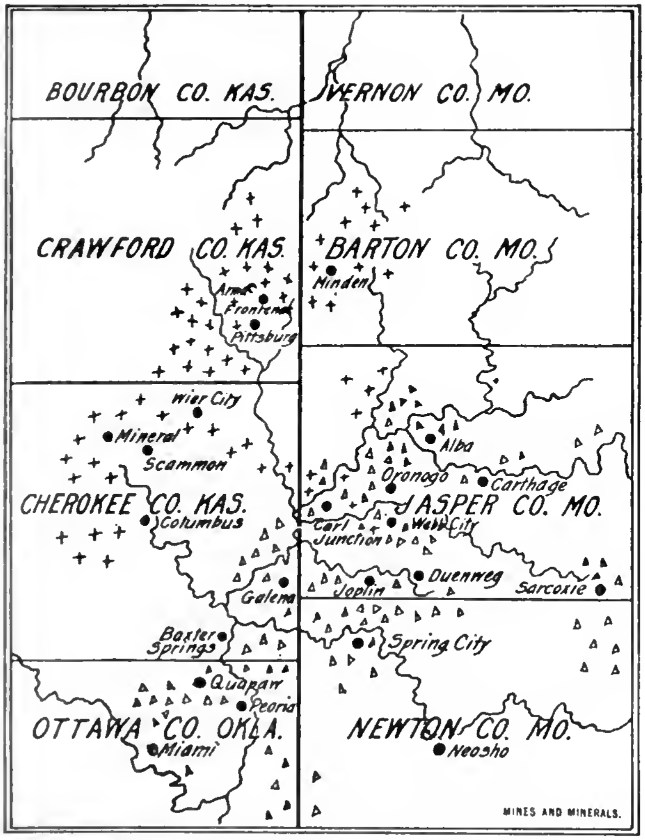

FIG. 1. COAL AND ORE ZONES OF KANSAS AND MISSOURI
Crosses, Coal Areas; Triangles, Mineral Regions

less than that of 1909, when the shipments aggregated 6,986,478 tons, with a valuation of $10,083,384. The miners' strike, which began April 1 and continued until September 15, caused a heavy curtailment of the production.

This coal district adjoins the Missouri, Kansas, and Oklahoma zinc and lead district, to which a considerable tonnage of the Kansas coal is shipped for consumption at the metal mines. In places the coal fields extend over into the ore belt, as is shown by Fig. 1, the crosses indicating the coal area while the triangles show the developed mineral regions. From this map it will be noted that the coal measures extend to within a few miles of Joplin, Mo., while, also, it will be noted that the ore deposits extend northward in Kansas, overlapping the well-defined coal belt. From several tracts in Jasper County, Mo., coal, lead, and zinc are produced from the same mine; the coal, although of medium quality as a rule, occurring in sufficient quantities to supply not only the fuel for the mine from which it is produced, but also furnishing cheap fuel for many surrounding ore mines, where the operators have been less fortunate in having their own coal beds from which to secure their supply.*

The Southern Kansas district is distinctive as the producer of an unusually good quality of coal in which the percentage of carbon is high; the Missouri, Kansas, and Oklahoma district is noted for the production of more than 55 per cent. of the zinc ore of the United States that is converted into primary spelter; yet, closely related as it would seem these two big districts might be, they are as widely different as day and night; the hypothetical line that marks the division between the coal belt and the ore belt that outlines the western fringe of the Mississippian series of rocks before it dips beneath the Pennsylvanian, also marks the division between a district that is purely American and one that is pronouncedly cosmopolitan. Foreign labor in the ore belt is the exception; the advent of foreigners is discouraged by the native employes, and, in a number of instances, when efforts have been made by mine operators to introduce foreign help, violence has resulted; for the American toilers look upon the zinc and lead zone as their own, and accordingly resent intrusion.

To go from the heart of the distinctly American ore mining community to the heart of the Kansas coal fields is a trip of barely an hour by luxurious electric palace cars, by train, or by automobile, but the brevity of the journey only emphasizes the astounding transformation. It is like journeying from New York to Italy in 60 minutes; it is a trans-Atlantic expedition in tabloid form, with all the unmistakable foreign atmosphere in evidence when the coal fields are reached. The tidy cottage of the zinc and lead miner is replaced with company settlements of severe box houses, close to one another, stringing across the prairies in painfully regular rows; even the landscape seems different; strange plants adorn the door yards; unfamiliar vines creep over the porches; odd-looking potted shrubbery graces the windows.

In the coal district the workman buys his own powder, at so much per keg, from the company that employs him or direct from the powder company; in the wash plants of the coal district, where a jigging process not unlike that employed in the ore mines, is used, the waste is the heavy portion that responds to the gravity treatment, while the marketable product is that which washes away.

While Crawford County is the heaviest producer of coal at present, Cherokee County formerly held this distinction. Early discoveries of coal were made in Cherokee County in 1867, the first production coming from mines near the state line east of Columbus. The later discoveries to the north resulted in a much superior article of coal being produced, as the early miners found a rather inferior grade of fuel, the depth of the deposits ranging from 40 to 80 feet, at which depth many of the mines of the extreme southern part of the south field are still being worked, while the mines north of Pittsburg are down to a depth of 200 feet. Leading coal companies operating in the Southern Kansas district are the J. R. Crowe Mining Co., the Sherridan Coal Co., the Fidelity Coal Mining Co., the Central Coal and Coke Co., the Columbus Coal Co., the Western Coal Mining Co., the Hamilton Coal Mining Co., the Mayer Coal Co., Clemens & Son, and other smaller concerns.

When the coal fields of this district were first prospected the general run of coal appeared to be confined to the immediate vicinity of Columbus and Scammon, but later developments showed the coal to extend from the southwest to the northeast, passing through Crawford County and up into Barton County, Mo. So numerous are coal mines now through the northeastern part of Cherokee County and the eastern part of Crawford County that it would be no easy matter to select a spot from which some coal mine could not be picked out with the naked eye.

* The editor has a piece of sphalerite attached to slate that was found in a Missouri coal bed.

The early part of 1910 saw operators pushing their production in anticipation of the labor strike which drew thousands of men from their jobs, leaving the coal producers helpless to meet the demands; hence, the surplus stocks of coal at the mines were enormous when the general walk-out finally was declared. Big mining companies and power companies of the Joplin district laid in enough fuel to carry them for months; railroads depending on the Southern Kansas coal in their traffic across the plains carried coal by the hundreds of thousands of tons to terminal points, where the fuel was heaped in gigantic piles to be used when the occasion demanded. But all supplies were well exhausted when regular production was resumed late in September.

The result of the strike was a victory for the workmen, whose wages were raised generally throughout the Middle Western States, Kansas being included. Miners now receive 75 cents per ton and furnish their own powder. A state law prohibits the use of dynamite in the coal mines, but this has proven to be a law that is violated. For turning a room off the entry the miner is allowed $2.37 additional to his fixed charge per ton for coal. Eight hours constitute a working day for all employes save the engineers, who work 9 hours. The drivers, cagers, track layers, and roustabouts receive $2.70 a day; top men receive $2.14 a day; shot firers receive $3.17 to $8.50 a day, the element of danger determining the amount. In especially dry, dusty mines where the shot firer momentarily is in peril of being converted into a blistered mass, the maximum wage will be paid, while the minimum amount will be his income in the safest mines of the district, where the air is moist and where there is little dust in circulation.

About 10,000 miners are employed in the Southern Kansas coal district, and of this number fully 40 per cent. are Italians, 20 per cent. negroes, and 40 per cent. Americans—all the miscellaneous clans of half-breed foreigners being included with the Americans. There are Scotch, Irish, Germans, Poles, Austrians, Swedes, Slavs, and representatives from almost every other nationality. For the most part the foreigners are jovial, generous, in some instances, to a remarkable degree, and excellent workers as a whole. Almost to a man they are thrifty, for almost to a man they have one crowning ambition: to return to the old country with their pockets bulging with American gold. Last spring when the strike went into effect the coal field representatives of the various steamship lines did a thriving business, and almost every train, for weeks after the strike was declared, carried homeward-bound travelers, eager to return to their native lands. Autumn witnessed a return of the excursionists to America, many of them bringing recruits to be initiated into the ways of the Americans, others bringing relatives. Intermarriage is common among the foreigners of various nationalities, and so it is that an oncoming generation is made up largely of an indiscriminate blending of the races.

FIG. 2. WASHERIES AT DUNKIRK, KANS.

The Southern Kansas coal district is a portion of what is known as the central bituminous coal fields, embracing the states of Missouri, Kansas, Arkansas, and Oklahoma. Around this area extends a zone, barren of coal, which depends to a large extent upon the coal production from the central fields. The states of Colorado, Dakota, New Mexico, and Wyoming, on the west; Ohio, Illinois, Indiana, Kentucky, and Pennsylvania on the east; and Alabama and Tennessee on the southeast, are the coal producing states surrounding the central fields.

The bituminous coal deposits of Southern Kansas yield the bulk of the fuel mined in that district, and in the state for that matter, although some semianthracite and lignite coals are found, the two latter types being little mined. These occur farther to the west.

The coal deposits, which are found outcropping at points along the Missouri-Kansas line dip gradually to the north and west. West of Pittsburg, Kans., open-cut mining is practiced on a limited scale, this type of coal mining having grown less in importance during the past few years, as many of the workable deposits have been exhausted. The line of outcrop of the coal deposits is from the southwest to the northeast. In the ravines the outcropping is especially noticeable, although on the higher elevations an occasional outcrop will be observed.

The thickness of the veins worked ranges from 2 feet 8 inches to 3 feet 6 inches; the roof, as a rule, being of shale. Some gas is encountered but not in sufficient quantities to cause inconvenience. Through the enforcement of a recent state law, all entries now are supposed to be 6 feet in height, and as the law is enforced rather satisfactorily, the old style low entry is rapidly disappearing. Much of the coal is shot from the solid, although efforts to abolish this method are being made.

Coal from Cherokee and Crawford County, and also from Bourbon County, to the north, comes from the Cherokee shales, the chief coal-bearing formation of the state, and one which extends westward, gradually attaining depth, but still containing coal, which eventually may be mined, although much deeper operations will be necessary to produce it. Erasmus Haworth, head of the Geological Survey of Kansas, says: "The abundance of coal within the Cherokee shales seems to be so great that it need not be a surprise if heavy beds be found under any part of the eastern 50 or 75 miles of the state."

Above the Cherokee shales occur the Labette shales, carrying no workable deposits of coal, and above these come the Pleasanton shales, carrying deposits of coal probably second to none save those of the Cherokee horizon. Above the Pleasanton shales come the Thayer shales, which likewise carry some coal; next the Lane shales with no coal; then the Lawrence shales, carrying coal in sufficient quantities to be mined at a profit in places. However, these occur much farther to the west and are not included in the Southern Kansas district.

The positions of the coal deposits within the Cherokee shales vary both vertically and horizontally. Near the extreme base of the shales, thin coal, unfit for commercial uses, is found. Farmers mine it for local consumption from numerous insignificant pits. About 150 feet above the base of the Cherokee shales a better coal bed is found. It lies under a heavy layer of sandstone and is directly covered with a thin layer of shale. But the heaviest coal deposits of the state are found in the Weir-Pittsburg lower and upper formations, the width of the lower run averaging 40 inches, while the upper will average 30. The first scientific recognition of the existence of these coals came in 1868, when a Chicago professor examined the outcroppings and rendered a favorable report, but for years prior to this time coal had been mined by the settlers and transported to the early lead camps in Newton County, Mo. In 1870 a railroad penetrated the coal belt and immediately the

demand increased. From then on, the railroads have consumed a large part of the coal produced, and today half a dozen lines depend on this district for their fuel supply to the north, the west, and the south.

Two lesser beds of coal, outcropping farther to the west, are found above the two Weir-Pittsburg horizons, but their commercial importance is insignificant compared to the more important formations. Another coal deposit, still higher, occurring at the very top of the Cherokee shales, is of some commercial importance and much coal from this level has been produced for commercial purposes, especially from mines in Bourbon County, north of the main Southern Kansas district.

Fig. 3. Jig Room in No. 2 Washery

Virtually all of the mines now running to any great extent in the vicinity of Pittsburg or Weir City secure their product from either the lower or upper coal beds of the Cherokee shales, although an intermediate layer exists, which sometimes is mined, although it is too thin as a rule to be worked at a profit.

The room-and-pillar system of mining is most common in the mines of Cherokee and Crawford counties, although the longwall system occasionally exists. The latter system is found convenient where the coal formation is unusually thin, but where the coal occurs in thicker strata, ranging in width from 3 feet upward, the room-and-pillar system has advantages. The thickness of the coal deposit makes it unnecessary to remove a great quantity of waste rock, as is the case where thinner strata are worked; therefore, the absence of the waste makes it imperative to find other material for support of roofs. It is customary to leave pillars of coal standing, to be removed later, at a time when the immediate workings are to be abandoned.

The double-entry method of operating the room-and-pillar system is employed in many of the Kansas mines. After the shaft has been sunk to a depth below the coal stratum to be worked, the greater depth being employed as a sump into which the mine waters drain, main entries, 12 feet wide and 6 feet high, are driven in opposite directions. On either side of the main entry, paralleling it, but separated by supporting walls of coal, are side entries. All three entries are driven to the boundary line of the property or coal.

From the side entries at intervals of about 100 feet, two parallel entries, 32 feet apart, are driven at right angles, and these extend as far as the workable deposits of coal occur, or as far as the property lines of the company permit. By this system of regular tunneling and cross-tunneling, the entire coal formation is blocked out and rooms are opened from which the larger tonnage of the mine's production comes. The entries are connected at intervals of 100 feet by breakthroughs, while between the two sets of double entries, cross-entries parallel to the side entries are driven and connect the two inner entries of the double sets. Such passageways, which aid in ventilation and which are used for hauling, are driven every 40 or 50 feet along the double entries.

The rooms, which are 35 feet from center to center, and which are worked to any length desired, are opened along the sides of the double entries opposite the pillars. Between the rooms, pillars about 11 feet wide are left, thus making the actual mined-out width of the rooms 24 feet.

Double tracking is used for hauling in the main and parallel side entries, the connections between the two being made at an angle of about 45 degrees. By alternating the openings from the main entry into the side entries at either side, the network of tracks is somewhat simplified, and the number of tracks coming out into the main entry at the same point is reduced. All entrances from the side entries to the main entry angle toward the shaft.

Where the single entry is used, only one main entry, with no side or secondary entry, is employed. Running from this entry, at right angles, are single entries, 100 feet apart, from which the rooms are driven.

Few supports of an artificial nature are required in the Southern Kansas coal mines. The roof, arched properly, is self-supporting as a rule, and timbering is required only where the coal is found beneath unusually soft shale.

In advancing a room, a series of cuttings are employed, obviating the necessity of placing a charge of powder into a solid face of coal. The first cutting is wide enough to permit the free action of a pick. The cut is extended about 3 feet into the coal face and reaches from the top to the bottom of the stratum. With the removal of coal from this small trench, space is left into which the coal can be forced when the charge is fired. Otherwise the blast would show a tendency to "squeal" or would result in a "windy" shot; that is, the coal face, instead of being broken into large, free chunks across the greater portion, would be reduced to dust in the immediate vicinity of the charge, and would not be affected some distance away from the charge. Where "horsebacks" are encountered, the miner receives additional pay for his labors; hence, the cost of mining where "horsebacks" are common is not only higher but the quality of the fuel is inferior.

In the majority of the mines, mules are still employed as motive power, and in virtually all of the mines mules are used in the side entries beyond the parting from the main entries.

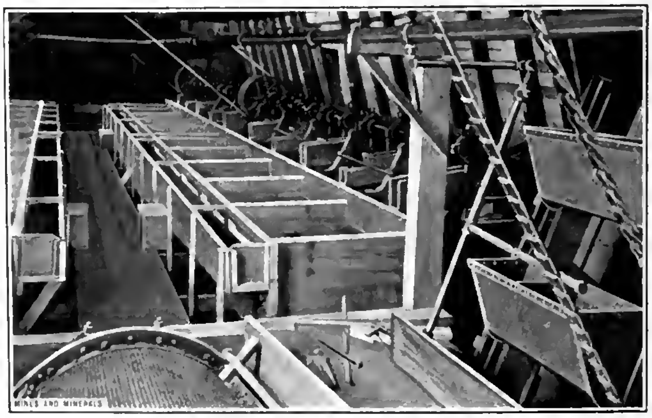

Fig. 4. Jig Room in No. 1 Washery

In some of the larger mines electric motors are employed in the main entries. It is the duty of the miner to load his cars and push them to the entry, where they are hooked on to the train of cars and hauled to the shaft. The underground hauls in some of the large mines are 3 to 4 miles in length, although the average is much less.

The introduction of coal washeries has greatly improved the coal of Southern Kansas. In the summer of 1908, the washery shown to the right in Fig. 2, was completed for the

Central Coal and Coke Co., at Dunkirk, in Crawford County, by the Link-Belt Co. The plant was constructed of creosoted lumber and timbers wherever exposed to water or weather. The contract covered the complete installation, including excavations, foundations, power plant, and a water system comprising supply for operation of the washery and for fire protection. The plant, while built for an average capacity of 125 tons per hour, was at times increased to 200 tons per hour, and even worked overtime to supply the demand for clean coal. By the use of this washery the company's business was increased to such an extent that in 1909 a second washery, shown to the left in Fig. 2, was ordered from the Link-Belt Co., and completed in September, 1910. The introduction of the jig in cleaning the coal has wrought great changes in the past 2 years. The interior of the jig room of the No. 2 washery is shown in Fig. 3, with the draining screen in the background. In Fig. 4 is shown the fine-coal jigs, draining screen, and elevator in No. 1 washery.

In the washer plants jigs are used that are not wholly unlike those employed in the separation of ores in the Joplin district. The jig consists of a rectangular box with hopper bottom, divided about half way down from the top by a partition. In one of the compartments a plunger operates. In the other compartment is fixed a screen plate. The jig tank is filled with water and the pulsating movement of the plunger forces the water up and down through the screen of the other compartment. The coal, in passing over the screen, is held in suspension by the pulsating current, and the lighter material, which comprises the marketable product, floats off of the screens, while the heavier material, which comprises the waste, settles to the screen and is drawn off by means of valves, save enough to form a sufficient bedding of waste material on the screens. Passing through the valves, the refuse falls into a compartment in the bottom of which is a gate through which refuse is drawn out of the hutch.

In the general operation of a fine coal jig, an artificial layer of feldspar is carried on the screen. The coal works its way across the top of the feldspar layer and flows over the end of the jig, while the heavier refuse gradually works down through the feldspar bed and screen into the hopper-shaped jig box, whence it passes out through a refuse sluice by gravity.

In the majority of the Southern Kansas plants the shaker screen system is employed; the coal, on being dumped from the cage, freshly hoisted from the mine, passing through screens of various sized mesh directly into coal cars, awaiting at the bottom of the chutes. That which passes over the 3-inch mesh is known as lump coal; that which passes through the 3-inch mesh, but which is too large to pass through 1-inch mesh, is known as nut, while that which passes through the 1-inch mesh is slack.

Lump and nut coal are now selling for $2 a ton, f. o. b. mine, while mine run brings $1.75, and slack $1.25. No briquetting has yet been undertaken in the Kansas field.

Owing to the unusually warm winter that has prevailed over the Middle West, the demand for coal for domestic purposes has been unusually light, and for this reason the operation of a great majority of the mines has been irregular, the result being that hundreds of men have been without employment some of the time. For commercial purposes, natural gas has taken the place of coal to a large extent in the ore mines of the Missouri-Kansas-Oklahoma district, and the use of gas not only in this ore-mining district, but throughout many of the leading cities of Eastern Kansas, has done more than any other one thing to reduce the demand for coal. However, the epoch of natural gas for commercial usages is waning in the Middle West, especially is this true of the gas produced from the Mid-Continental fields of Southern Kansas; for, although the claim is made by the gas companies that the supply is as great as ever, the shortage is painfully in evidence when the weather becomes severely cold, and under such conditions it is not uncommon for the gas companies to order the discontinuance of gas for all save domestic purposes.

More than a year ago the metal-mine operators of the Joplin district began to realize what it was to receive an immediate order to discontinue the use of gas under boilers. Sometimes weeks would elapse before gas for boilers could be secured. The price of gas per 1,000 cubic feet has been raised to 25 cents, the same as for the domestic consumers. However, with warm weather, the rate has been lowered. It is the uncertainty of the natural gas supply for other than domestic usages that is causing many mine operators, manufacturers, and others to return to the use of coal or to adopt the newer power, electricity, which is beginning to play a conspicuous part in the commercial development of Southwestern Missouri, Southeastern Kansas, and Northeastern Oklahoma.

A WARNING TO COAL MEN

By Erasmus Haworth, State Geologist, of Kansas

The recent disaster following a gas explosion in mine No. 16, at Mineral, Kans., where five lives were lost on account of an erroneous belief on the part of both operator and miner, compels me to issue a warning to all others similarly situated. I do this in the hope that ultimately lives and property may be saved. We have no state law directly throwing any responsibility on me in this and similar cases, but there is a higher law of human love and human sympathy which in a degree will condemn me if I remain quiet. The explosion occurred about 5 o'clock on Saturday afternoon, March 18, 1911. The day's work had been completed and three shot firers went below to fire the shots. One of them reached the surface with almost no injury, but the other two were killed. As soon as it was known that something had gone wrong the superintendent, Mr. Joplin, with two assistants, rushed below, whereupon another explosion occurred which destroyed their lives.

The Lesson To Be Learned from The Explosion at Mineral, Kansas, in a "Non Gaseous" Mine

Previous to this no explosion had occurred in this mine, nor in this immediate vicinity. It was confidently believed by Superintendent Joplin, and by all the miners, that no gas whatever existed in the mine. The mine floor was unusually wet and muddy, so that they believed there could be no danger from dust explosion. With these beliefs firmly fixed in their minds, apparently no special precaution was used or had been used to guard against explosions. Every one underground carried ordinary lamps, because there was no danger from explosion. Even when Mr. Joplin and his party went to the rescue they did not carry safety lamps, the belief in safety from explosion being so thoroughly fixed in their minds. When I visited the mine a few days later I found an abundance of safety lamps belonging to the company, showing that Mr. Joplin might have provided himself with them had he deemed it necessary, or even advisable.

Mine No. 16 is fairly well developed, and at this time was worked to the north of the shaft. The old and abandoned mine No. 7 lies to the north and northwest, so that shaft No. 7 is from a mile to a mile and one-half northwest of shaft No. 16. From the foot of shaft No. 16 the entry leads 875 feet to the north, then 700 feet east, then 900 feet north. Throughout this last 900 feet two main entries had been driven about 30 feet apart, with only a few doorways cut through the coal between them. Seventeen rooms had been developed on the outside of each of these entries. Two of the shot firers presumably went together to the extreme north end of these two entries, when one of them began firing the shots in the rooms lying east of the east entry and the other one began firing the shots in the rooms to the west of the west entry. If they had worked with equal speed the two should have come out at the south end of these two entries about the same time. It so happened, however, that the shot firer on the east outran his companion, and had fired the shots in all 17 of his rooms before the explosion occurred, while his companion had completed firing only the shots in the north 11 of his 17 rooms.

Now, it seems that the first shot for the east entry broke through into the old workings of mine No. 7, and this is what caused the disaster. It is reasonably sure that explosive gases had accumulated in mine No. 7 during the time it had been idle and that these gases rushed through the opening made by the first shot and mixed with the fresh air in mine No. 16, and that the shot firer, on account of his speed, was able to have traveled this entire 900 feet before the southward migration of the explosive gas overtook him. But finally it did overtake him and was ignited either by a flame from one of the last shots he fired or by the open lamp which he carried.

Mine No. 7, the same as No. 16, was supposed to have been entirely free from gas, and further, was a wet mine, so that there could be no danger from dust explosion. The coal was reached in No. 16 at 60 feet from the surface, while at shaft No. 7 it was 110 feet from the surface. The point of meeting of the two mines near where the explosion occurred was approximately midway between the two shafts. The floor of the old mine No. 7, therefore, rose approximately 25 feet from the foot of the shaft to the wall which was broken through by the shot above described. No. 7 had been abandoned for years, during which time it had filled with water considerably more than enough to form a water joint at the foot of the shaft. In this way the air and gas in the mine southeast of the shaft was carried southward toward mine No. 16. How much pressure would be generated by this process as the water gradually accumulated in mine No. 7 would depend entirely upon the height of the water in shaft No. 7, which is a point of fact I have not yet learned in detail. However, it is well known that the water was a number of feet deep and subsequent events showed that the air and gas were under pressure, probably at least 2 or 3 pounds per square inch above that of the air in mine No. 16.

As time passed after the shot the pressure in the old mine would gradually become reduced by the escape of gas and air into No. 16, and ultimately would become the same in the two mines.

We know first, that with comparative suddenness conditions were changed throughout the northern part of mine No. 16 so that a number of explosions occurred. Mr. Gilday, State Mine Inspector, was called from Pittsburg, and reached the mine about 2 o'clock Saturday night. Immediately he went below and worked his way northward, ultimately reaching the face at the northern extremity, and found the opening which had been broken through into the abandoned mine No. 7. His statement is that at this time, fully 7 hours after the explosion, he found a hole there approximately 8 to 12 inches wide and from 3 to 4 feet long through which air was rushing so rapidly that it was with the greatest difficulty he could stop up the hole by any means at his command. He used canvas and hay and anything he could get hold of in the mine, and finally succeeded in holding these obstructions against the opening and piling masses of coal against them until practically no further exchange of air occurred. He suspected at once that this was the cause of the trouble and made arrangements to clear these northern parallel entries of gas as rapidly as possible by shifting the direction of the air and by increasing the action of the fans.

As late as Tuesday afternoon, March 21, substantially 72 hours after the explosion, some natural gas was still lingering in these entries. A careful examination of the ground showed that the east one of the two entries was swept clean by the onrushing action of the air at the time of the explosion, while the west one showed decidedly less effect of the explosion. The mine inspector reported that during Saturday night and Sunday, from time to time, when in the west one of the two parallel entries, he would force the canvas away a little at a doorway connecting the two entries and would insert his safety lamp a foot or more into the east entry, through which he now had a strong current of air driven by the fans, and that for more than 24 hours after he reached the scene the lamp showed that there was sufficient gas in the east entry to be dangerous. He also found from these and other similar tests that the amount of gas in the east entry gradually diminished until the conditions were reached, as already mentioned, on Tuesday afternoon, the 21st.

It was early tests of this character which determined the mine inspector's actions, to force free air northward into the west entry as rapidly as possible, and carry it entirely to the north wall of the mine, then carry it through to the east entry and force it back south, hoping in this way to carry out of the mine the gases which had entered the east entry in such large quantity. The mine inspector acted with the best of judgment in the way he located the seat and cause of the trouble, and in the methods he employed for righting the difficulty.

During the period between the first explosion and the time Mr. Joplin and his associates reached the south end of the east entry, a fresh amount of gas had migrated southward from its supply store in No. 7 and was mixed with fresh air supplied by the fans to the extent of producing an explosive mixture, so that the lamps which Joplin and his associates carried caused this second explosion.

The fundamental error made by every one connected with mine No. 16 and mine No. 7 is the assumption that no explosive gas would accumulate in either of these two mines. This error is the one which has called for this present report. I wish to emphasize with all the power at my command that nobody has any right ever to assume that dangerous gases will not accumulate in a coal mine. An historical study reveals the fact that "firedamp" or natural gas, is liable to occur in any coal mine.

Any abandoned mine of any nature whatever, which has prop timbers or any organic rubbish, sooner or later becomes dangerous. The danger is vastly greater if the mine is in stratified rocks and in any way connected with coal or carbonaceous shale.

Apply this to old shaft No. 7, a mine which while being worked either gave no gas or so small an amount that the ordinary ventilation kept the mine free from dangerous quantities. This same mine is abandoned and in the course of time is opened up under such peculiar conditions that the air and gas are found to be under extraordinary pressure. Here are two elements of danger—one from gas and the other from the extraordinary pressure under which it exists.

It is recommended that no one ever assume that any coal mine is free from firedamp, or natural gas. It is a most dangerous assumption. A mine may have so small an amount of firedamp in it that ordinary methods of ventilation will prevent its becoming dangerous while ventilation is kept up to a proper degree. Any shot at any time in any mine is liable to break into a gas reservoir and permit a dangerous amount of gas to rush into a mine. This has occurred over and over again in Kansas and elsewhere. But it is vastly more dangerous to assume that an abandoned mine, or an abandoned part of a mine being operated, will remain free from gas. Don't make such an assumption.

It is recommended that all mine operators at once make provisions for relieving the air pressure in all abandoned mines which are at all likely to be broken into by development in adjacent mines. This can be done easily and cheaply by drilling one or more holes from the surface into the part of the abandoned mine where the roof is the highest. Suppose, for example, that a 6-inch hole had been drilled from the surface into the abandoned part of mine No. 7 at Mineral. Then accumulation of water in the mine could not have caused this extra pressure in the air left in the abandoned mine, and, as a result, even though the gas were there it would not have rushed through into mine No. 16 the way it did, and therefore the explosions could not have occurred. Care should be taken to drill these vent holes so that they will tap the abandoned mine at places where the roof is the highest, and a large drill bit should be used, so as to make a large hole, not less than 6 inches, and larger if possible. The drill hole should be cased so it will remain open permanently.

Now, as natural gas is lighter than air, the gas which is likely to accumulate in all abandoned mines will escape first through the drill hole, and later such air will escape as is necessary to prevent an excess pressure should water enter the mine. This is a simple remedy, and I fear on account of its simplicity will not appeal to operators and miners as it should. But I consider it important, as human life and human property are valuable.

All operators and all miners should require a drill hole to be kept in advance of development wherever development approaches an abandoned mine. This has been enacted into law in many states on account of the well-known fact that gases do accumulate in abandoned mines. Had it been obeyed in this case enough gas would have rushed through the little drill hole to give an alarm, and more than likely the explosions would not have occurred.

RAIL BONDING IN MINES

*Written for Mines and Minerals, by Vincent Rhea**

The writer has recently had occasion to test the rail bonding in a number of mines in the Pennsylvania bituminous coal district. The result of these tests, and the methods adopted to remedy the troubles found, should be of interest to every mine manager using electric haulage, particularly those who are not utilizing the full value of their return circuit, and who consequently have an excessive drop in voltage and various motor troubles due to the difference in potential between trolley and rail.

While a few operators are using modern methods of bonding, the majority are depending on channel pins and wire to carry the return circuit. The channel pin when first installed is more or less efficient, but as three-fourths of its contact is between steel pin and steel rail, it is impossible to obtain a union that will exclude air and moisture. Therefore it is only a short time until corrosion has started and a high resistance is introduced at the points of contact. The method of testing prevalent at most mines consists of examining the bond to see that the wire and pins are intact.

The return circuit of a mine that was bonded partly with channel pins and partly with compressed-terminal flexible-cable bonds was tested with a direct-reading bond tester which showed the resistance of each joint as equal to the resistance of a certain length of solid rail. Thirty-one per cent. of the channel-pin bonds showed a resistance equal to or greater than that of 30 feet of rail, or practically an open joint. The average resistance of the balance was equal to that of 13 feet of rail. These channel pins had been installed about 2½ years, and on an exceptionally good roadbed.

The compressed-terminal bonds had been installed 4 years on a roadbed that was in bad condition. The drainage was bad and the soft bed permitted a considerable rising and sinking of each joint when a car passed over, thus imposing a severe strain on the bond terminals; 16 per cent. of these bonds were found defective, the balance showed an average resistance of 6.6 feet. Had these bonds been installed in track similar to that in which the channel pins were used there is no doubt but that the depreciation would have been cut in half.

What particularly impressed the writer in making this test, was the fact that the majority of the compressed-terminal bonds were in good condition after 4 years of service, and under unfavorable and rather uncommon conditions. Had this company tested these bonds at certain intervals, and replaced defective ones as found, they would have had, at a small expense for labor and material, a highly efficient return circuit at all times.

This operation had been suffering from an excessive drop in voltage, and the results of this test proved conclusively that it was caused by a defective transmission of the return current. The channel-pins in this mine are being replaced by compressed-terminal flexible-cable bonds which show an average resistence of 4.5 feet, and the management has decided to discontinue the use of channel pins.

The relative resistances of 21 joints selected at random along the haulage system of this mine, bonded first with channel-pin bonds then with compressed-terminal bonds, are clearly shown in the accompanying curve.

One mine manager reported that, with sufficient copper overhead, he found a drop of 100 volts, at less than 3,000 feet from the generator on a 250-volt direct-current circuit. The

* Mining Department, Electric Service Supplies Co.

channel-pin bonds in this mine were tested, and 90 per cent. of of them found to have a resistance greater than that of 30 feet of rail. The channel pins were replaced by compressed-terminal bonds, the line voltage went up to normal and the efficiency of the locomotive increased to a marked extent.

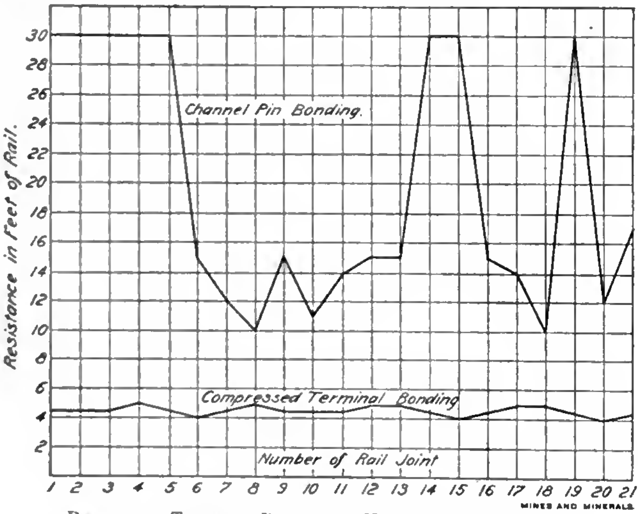
Tests of other operations where low voltage and motor troubles were prevalent showed in every case very defective bonding due to the use of channel pins.

While engineers and electric railway operators fully appreciate that the utilization of the full carrying capacity of the rails for the return circuit is of as great importance as the overhead construction, it is a matter that most mine managers have given little attention.

The bonding of the rails of an electric haulage system is of the utmost importance if the full efficiency of the generating plant and the motors is to be realized.

The compressed-terminal flexible-cable bond properly installed makes an absolutely moisture-proof contact between the rail and bond, and barring mechanical injury should have a long life without any material decrease in efficiency. The flexible cable takes care of the jar and vibration caused by a trip of cars passing over the joint, thereby imposing no undue strain on terminals.

If mine managers, particularly those who are using 250 volts for their haulage, and getting farther away from their source of power every day, will install bonds of this type, and give them the attention their importance deserves, they will find that they have at all times a highly efficient return circuit, and are getting the full value of their equipment, which usually means "increased tonnage."



RESULT OF TESTS OF DIFFERENT KINDS OF RAIL BONDING

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals by J. T. Beard

Hoisting Engineers' Examination, Held at Des Moines, Iowa, December 6, 7, 1910

QUES. 1.—State your experience with engines and boilers around Iowa mines.

QUES. 2.—(*a*) What is a unit of heat? (*b*) What heat unit is commonly used in the United States?

ANS.—(*a*) A unit of heat is such a quantity of heat as is required to raise the temperature of a unit weight of pure water, at its maximum density, 1 degree of a specified scale. (*b*) The heat unit commonly employed in the United States is the British thermal unit (B. T. U.), and is the quantity of heat required to raise the temperature of 1 pound of pure water, at 39.1° F., 1 degree of the Fahrenheit scale.

QUES. 3.—How far must a 75-pound weight be placed from the fulcrum of a safety valve that has an area of 4 square inches, the valve stem being 3 inches from the fulcrum, so that the steam will blow off at a pressure of 100 pounds per square inch?

ANS.—Disregarding the weight of the valve, valve stem, and lever, which is not given, the required distance is

$$x = \frac{3(100 \times 4)}{75} = 16 \text{ in.}$$

QUES. 4.—Give a complete code of hoisting signals.

ANS.—A code of hoisting signals adopted for use at mines is as follows:

1 bell, *hoist* when cage is at rest; or
stop when cage is in motion.

2 bells, lower cage.

3 bells, men want to be hoisted. (It is the duty of the topman when this signal is received to give an empty cage and return a signal of 1 bell to the bottom and at the same time ring a jingle bell in the engine room. The engineer should then notify the bottom man by a blast of the whistle or by a signal of 2 bells, that he is ready to hoist men. The men are then allowed to get on the cage, and when all is clear the bottom man gives 1 bell to hoist. The engineer only moves the cage in response to the signal of the bottom man (the topman signals the engineer with a jingle bell). The bottom man must never signal the engineer, in any case, till he has received 1 bell from the topman signifying that all is clear at the top. If the topman cannot hear the engine-room bell, or fails to respond promptly to signals from the bottom, the engineer may repeat the signal by sounding the whistle.

4 bells, stop at lower landing; followed by the usual signal of 1 bell to hoist.

5 bells, hoist or lower slowly and with extra caution, followed by usual signal to hoist or lower, as desired.

6 bells, change cages.

QUES. 5.—Define the following terms: Combustion; dead center; lead; tensile strength; factor of safety.

ANS.—Combustion is any chemical reaction causing a change in the physical condition or state of a substance and accompanied with the evolution of heat and often producing light or flame, or both. The most common form of combustion is oxidation. Dead center is a term used to describe those positions of the crank-arm of an engine in which the piston can exert no turning moment on the crank-shaft. Lead, in engine practice, is the amount the port is open when the crank is on dead center. Tensile strength is the strength of any given material to resist a pull or extending force, per square unit of cross-section. Factor of safety is the ratio of the ultimate or breaking strength of any material to the allowed working strength of that material; or the ratio of the breaking load to the allowable safe load of any structure or member.

QUES. 6.—Find the indicated horsepower of a single-cylinder engine having a piston 10 inches in diameter and a stroke of 12 inches when the crank makes 120 revolutions per minute

and the mean-effective steam pressure is 60 pounds per square inch.

ANS.—

$$\text{I. H. P.} = \frac{60(.7854\times10^2)12\times2(120)}{33,000\times12} = 34.27, \text{ say } 35 \text{ H. P.}$$

QUES. 7.—Describe the proper method of lining the crank-shaft of an engine.

ANS.—The method to be employed will depend on circumstances. What is to be determined is that the axis of the crank-shaft, in a horizontal engine, is level and set at right angles to and in the same plane with the center line of the cylinder. It will not be possible to apply the same method to all types or styles of engines. Assuming that the crank-shaft is in place, its horizontality may be tested by an ordinary spirit level, or by suspending a fine plumb-line from the end of the crankpin in its uppermost position and marking the exact position of the point of the bob or of the line below, and checking by repeating the operation when the crankpin has been brought to its lowermost position. If the two marks exactly correspond, the axis of the shaft is horizontal. To ascertain if the crank-shaft is square with the center line of the cylinder it is often better, or even necessary, to take off the cylinder heads and remove the piston and the crosshead and stretch a fine wire taut through the exact center of the cylinder, adjusting the line till its true position is obtained. Measurements from this line to the face of the crank-arm at the two dead centers will determine if the shaft is square with this line or not; if it is square with the line the two measurements will be exactly the same. By means of a steel square placed against the face of the crank-arm or disk in a vertical position it can be shown whether the axis of the shaft lies in the same plane with the center line of the cylinder.

QUES. 8.—What steam pressure should be allowed in a boiler 60 inches in diameter, made of $\frac{3}{8}$-inch steel plate having a tensile strength of 65,000 pounds per square inch when double riveted; using a factor of safety of 5?

ANS.—A safe rule in common use in boiler practice, is to allow 70 per cent. as the efficiency of a double-riveted longitudinal joint. This gives for the safe allowable pressure in this case,

$$p = \frac{.70\times65,000\times\frac{3}{8}}{30\times5} = 113.75 \text{ lb. per sq. in.}$$

QUES. 9.—How much farther does the crankpin of an engine travel than the piston when the stroke is 36 inches?

ANS.—

$$3.1416\times36 - 2\times36 = 41.0976 \text{ in. each rev.}$$

QUES. 10.—Under what conditions is a second-motion engine to be preferred to one that is coupled direct?

ANS.—In hoisting from shallow shafts where the speed of hoisting does not exceed, say 800 feet per minute, and in sinking operations, and all haulage engines for operating rope haulage, geared or second-motion engines are generally preferred.

QUES. 11.—How would you set and brick in a boiler to allow all its parts to move under a change of temperature?

ANS.—The best method is to hang the boiler from two independent gallows-frames, each consisting of two upright channel bars or legs supporting a cross-bar or **I** beam. The channel bars are built into the brick walls enclosing the boiler, and asbestos packing is used to close the space between the boiler and sidewalls, while a slip-plate attached to the rear end of the boiler and resting on the end wall closes the flue at this point and allows for the free expansion of the boiler.

QUES. 12.—What is saturated steam?

ANS.—Steam that is at the point of condensation, or that will deposit moisture on the slightest reduction of temperature

QUES. 13.—What is one of the most marked characteristics of steam?

ANS.—Its expansive force.

QUES. 14.—In taking up the wear of the connecting-rod brasses what must be done to keep the proper length of the rod?

ANS.—A shim of this metal must be placed behind the brass on the opposite side of the pin from the wedge. The thickness of the shim must be equal to one-half the wear, the wedge being driven in to take up the other half.

QUES. 15.—What are the sources of loss of heat in a steam engine?

ANS.—Condensation of steam, and radiation and conduction of heat.

QUES. 16.—What is a steam jacket?

ANS.—A steam space or chamber surrounding another chamber or receptacle, having for its purpose the retention, as far as possible, of the heat of the inner vessel.

QUES. 17.—How may loss of heat in the exhaust of an engine be lessened?

ANS.—(1) By conducting the exhaust steam into a feed-water heater and thus utilizing its heat. (2) By exhausting at a lower pressure, either by use of a condenser or by increasing the expansion of steam in the cylinder by an earlier cut-off.

QUES. 18.—What is back pressure?

ANS.—By back pressure, in steam-engine practice, is meant the pressure under which exhaust takes place from the cylinder, and caused by the resistance of the steam ports and valve to the escaping steam; or the steam pressure that resists the forward movement of the piston.

QUES. 19.—The piston speed of an engine 420 (feet per minute), the number of revolutions 110; what is the length of stroke?

ANS.— $$\frac{420\times12}{2\times110} = 22.9+ \text{ in.}$$

QUES. 20.—If the length of stroke of an engine is 2 feet and the piston speed 800 feet per minute, what is the number of revolutions per minute?

ANS.— $$\frac{800}{2\times2} = 200 \text{ rev. per min}$$

BANNER MINE EXPLOSION

Robert A. Neill, Associate Mine Inspector, reported to the Governor of the state of Alabama on April 20, his investigations and conclusions in regard to the explosion which occurred at the Banner mine on the morning of April 8, at 6:35 A. M., when 128 men, mostly convicts, lost their lives. From this official report we deduce the following:

The mine is operated by the Pratt Consolidated Coal Co., and is situated in the extreme western part of Jefferson County, about 20 miles from Birmingham, on the Cane Creek Division of the Louisville & Nashville Railroad. The Banner mine operates on the Big Seam and is 140 feet deep. It gives employment to 285 men, 250 of whom are inside miners, and 35 work on the outside.

The capacity of the mine is approximately 1,100 tons of coal daily. The mine has three openings, known, respectively, as the slope, No. 1 shaft, and No. 2 shaft. At No. 1 shaft there is a 17-foot diameter Crawford & McCrimmon fan used only in case of emergency. At No. 2 shaft there is a 20-foot diameter fan of the same make, which furnishes from 180,000 to 200,000 cubic feet of air per minute. This furnishes about 800 cubic feet of air per minute to each man, and to overcome the extraction of moisture from the mine by the air, 96 water sprays were distributed throughout the mine at intervals of 100 feet apart, each delivering 30 gallons of water per hour in the form of vapor. This vapor is carried throughout the mine by the air-current and deposited on the walls, roof, gobs, and floor of the mine.

The headings in this mine are driven 7 feet high by 18 feet wide, carrying with them a gob of 9 feet by 5 feet, which leaves a sectional area of from 75 to 85 feet for haulage and ventilation. The air courses have the same sectional area as the headings. The split system of ventilation is used throughout. All overcasts are built of concrete, the floors being 2 feet in thick-

ness and the arch from 6 to 8 inches in thickness. All brattices are built of stone and cement 18 inches in thickness. No doors are used in the ventilating system, thus making it impossible to interfere with the ventilation at any part of the mine by leaving doors open, which would permit the air to short-circuit. So long as the ventilating fan was kept in operation the ventilation could not well be interfered with and the automatic fan recorder shows the fans to have been in operation regularly and continuously up until the minute of the explosion.

In this mine all coal was undercut by electric machines before blasting was done. As is the usual case in machine mining, considerable dust is made, and the air in the immediate neighborhood of the machines was very dusty when they were in operation. To meet this condition, in addition to the moistening appliances, all dust not in suspension in the air was loaded in cars and sent out of the mine before any blasting was done in places where machines were at work. It was the custom for a free man to have under his charge three or four convicts. This man had control of two working places, in order that loading in one place could be done while the machines were undercutting in the other. The blasting was done by shot firers, each heading having separate shot firers who prepared the charges and fired them while the miners were in the mine.

The explosive used was Bituminite No. 1, a permissible explosive that was carried into the mine daily in quantities to do a day's work. This was distributed so that each entry had its proportionate supply. But the quantity necessary for daily use in each heading was kept together so that from 25 to 100 sticks were in each place of storage. Bituminite is a permissible powder, which successfully passed the test of the United States Testing Station. Its base is nitroglycerine, and its composition is such that a spark from a mine lamp or other source might set it off. The Banner mine generates gas, but not in large quantities, as is shown by the daily reports of the fire bosses; and the large quantity of air circulated would indicate that gas was not the agent which extended the explosion, even if the possible ignition of a pocket of gas might have originated it.

The force of the explosion up to the air-shaft failed to show evidence of heat, that is, scorching on the shaft timbers, as in the case of Virginia, Mulga, and Palos mine explosions. At each of the latter places flames shot out of the mines and the explosive gas was found when recovering the dead bodies.

There were 50 men who escaped the firedamp in the Banner mine. The machine men and their helpers and the bosses had not yet entered the mine, with the exception of O. W. Spradling, under foreman, and Lee Jones, a shot firer, both of whom were killed.

After a thorough examination of the mine, Mr. Neill arrived at the following conclusion as to its origin and cause:

"The disaster originated by a premature explosion of Bituminite at the magazine located in the cross-cut between the entry and air-course about 21 feet inside of room No. 17 on the seventh left heading. I am led to this conclusion because of the fact that the force of the explosion was divided here, traveling in the direction of the heading face and also in the outer direction toward the slope."

That some Bituminite exploded at this plant is evidenced by the fact that the records of the mine officials show that 160 sticks of Bituminite should have been found in this locality, made up of 40 sticks left over from the previous shift, 20 shots made up ready for use, and 100 sticks carried down that morning by a shot firer. The body of one of the shot firers for the seventh left entry was found in the near neighborhood of the magazine badly mutilated, and there was evidence of greater force and heat in this entry than in any other.

The evidence, as shown by coke deposited on the timbers, cars, walls, etc., leads to the conclusion that the premature explosion of the Bituminite occurring in the magazine in the seventh left entry aided by dust was the direct cause of the disaster.

Inspector Dickerson, who also examined into the accident, in his report does not agree with Inspector Neill as to the initial cause. While Inspector Neill attributes the initial cause to the explosion of the Bituminite, Inspector Dickerson says: "I examined the place carefully, but failed to find any indication of any powder having been exploded, either there or elsewhere in the mine." He bases this conclusion on the fact that if such a quantity as 160 sticks of Bituminite had exploded there would have been an indentation in the floor of the room in which the explosion occurred. While the reports of these two capable men differ as to the probable cause, the conditions existing previous to the accident favor the conclusions of Inspector Neill.

In the first place the mine was well laid out and the ventilating current was sufficient to dilute and carry off the comparatively small amount of gas evolved, especially from the live workings. The accumulation of 160 sticks of Bituminite at one place, 100 sticks of which was being taken in by one man, was in itself a menace to safety. A spark from the shot firers' lamp or from some other cause could easily ignite it, and while it was a permissible powder in the meaning of that term as used by the United States Testing Station, it would produce such a stirring up of dust and so much flame and heat that the dust could easily carry the explosion to distant parts of the mine, especially as the practice of driving the headings 18 feet wide and gobbing 9 feet of this width made a great receptacle for dust, which could not be effectively dampened, even by the extensive vaporizing system used. Had it not been for dry dust, such as would naturally be thick in the gob, and probably in other comparatively inacessible places, the initial explosion would have probably affected only a limited area of the mine. The practice of taking in the explosive, as far as limiting the amount to the quantity required for each shift, was all right as far as it went, but the practice of storing all required for each heading in one place was radically wrong, and it is a great wonder that the supply stored in each of the other headings did not explode and make the damage to the mine, at least, far greater than was the case. Familiarity through constant use of explosives frequently makes men careless in handling them, and it is possible that the shot firer who had with him 100 sticks of Bituminite was not as careful as he should have been, and he not only lost his own life, but caused the death of 127 others. That the explosion did not extend through all the workings instead of through only a portion of the left heading was undoubtedly due to the vaporizing system keeping the dust in the main haulage road damp enough to prevent the flame carrying into the right headings to any serious extent.

TRADE NOTICES

Telephones in Mines.—The Western Electric Co., of New York, among its recent installations of mine telephones, has equipped the mine of the Springfield Coal Co , at Springfield, Ill., with a system of eight telephones of the ironclad type, which were specially built for mine service. One telephone is located in the engine room on the surface, one at the foot of the shaft, and the other six at convenient points in the mine about 1,000 feet apart. The chief use of the installation is in the systematic operation of the mine haulage and the direction of the underground work generally. In addition to the convenience and facilities for expediting work, this system is a great safeguard as a means for notifying the officials and men of any stoppage in work, accident, or possible danger that may necessitate the speedy withdrawal of the men from the mine.

Electric Mine Hoist.—The St. Clair Coal Co., at St. Clair, Pa., has just installed an electric hoist built by the S. Flory Mfg. Co., of Bangor, Pa. This hoist is equipped with a drum 6 feet in diameter by 5 feet 6 inches between the flanges. A special

feature is the application of the Werner patent band friction, which is operated by an electrical air compressor equipment. When the friction is thrown in contact, it will remain in position until released. The drum and gear form a unit and can be operated as a reverse-motion hoist without any end strain on the bearing. After the friction is released, the drum is loose on the shaft and will revolve freely at high speed when lowering or paying out rope. There are a number of new and advantageous features embodied in the Flory electrical hoists, which are constructed with single drums or two drums placed either side by side or tandem.

Coke-Oven Equipment.—The Mining and Coking Equipment Co., with main offices in Pittsburg, Pa., has recently been incorporated under the laws of Pennsylvania. The company will, beside manufacturing and selling the Beutlich coke oven door and other equipment, design special requirements of the mining and coking industry. The officers are A. F. Ehrenhaft, president, and Richard F. Beutlich, secretary and treasurer.

President of Westinghouse Company.—John F. Wallace, formerly chief engineer of the Panama Canal, who retired after inaugurating the American work on the canal, has assumed active charge as president of the Westinghouse, Church, Kerr & Co., who were the engineers for the new Pennsylvania station in New York. Mr. Wallace also acted as railway expert for the reorganization committee of the Seaboard Air Line, which was reorganized on the basis of his report and the prospertiy of this railroad since its reorganization has more than justified his conclusions and predictions as to its earning capacity. Mr. Wallace succeeds Mr. H. H. Westinghouse.

New Office.—The Mineralized Rubber Co. announce the removal of their offices to 165 Chambers Street, New York City.

Memorandum Books.—Chas. C. Moore & Co., engineers, San Francisco, Cal., are sending engineers neat perforated memorandum books worth having. Send for one.

The Weber Subterranean Pump is a distinct advance in the line of simple and effective pump mechanisms. It is not only effective, but automatic in action. It is operated by compressed air and can be adjusted for starting and stopping at predetermined water levels in the sump when used for mine drainage; or when in use for deep well pumping it can be adjusted to stop when the water in the storage tank reaches a predetermined height. A strong feature of the pump is in the economy of power used in its operation. The height to which it will pump water is dependent on the pressure of the compressed air; with a pressure of 125 pounds it will theoretically pump about 300 feet, but the manufacturers, to be on the safe side, advise 200 feet, although, by compounding, it can be made to pump to any desired height. An attractive circular, illustrated with sectional views, showing the operation of the pump, is issued by the manufacturers, the Weber Subterranean Pump Co., 90 West Street, New York City, and is worth the attention of mine managers generally.

Electric Mine Lamp.—The use of incandescent electric lamps by mine officials and miners has long been considered to be a great advantage in mining operations, both as regards convenience and safety, provided such a lamp, with its supply of electricity, could be practically self-contained and capable of being used in any part of the mine, and be as portable and convenient to move around as an ordinary mine lamp. This desirable feature has been attained in the Pilley electric mine lamp which can be worn on the cap or hooked to any part of the clothing. In addition to furnishing a brilliant light, without smoke and without flame coming in contact with the air, it is economical in operation. The battery furnishing electricity for the lamp is simple and is armor clad, so that it cannot be broken or damaged. It can be carried in the pocket or fastened to the belt without in the least interfering with the free movements of the workman wearing the lamp. A number of mine managers have already commended this lamp in the highest terms after giving it a thorough trial. Full information as to the use, cost of operation, and maintenance of Pilley lamps, will be sent to readers of MINES AND MINERALS who will write to the Westfalia Engineering Co., 42 Broadway, New York City, or the Pilley Mfg. Co., 608 South Third Street, St. Louis, Mo.

Electric Plant of Victor-American Fuel Co.—The Victor-American Fuel Co., which owns one of the most up-to-date coal-mining plants in the Southwest, and operates steam plants at three of its coal properties near Gallup, N. Mex., is installing a central turbine plant to transmit power from this to its other properties. The plant consists of a fireproof brick power house, with steel-supported roof in which are installed one 300-horsepower water-tube boiler, and three 100-horsepower marine boilers with Illinois stokers, space being left for additional boilers to be installed later. Steel coal bunkers receive coal from a tipple about 200 feet away. The ashes from each boiler fire-pot are emptied into a special car underneath the boilers and these cars are run out and the ashes emptied into a pit from which they are conveyed by an aerial tramway to an ash dumping ground some 2,000 feet away.

In the generator room, the present installation consists of two ATB 500-kilowatt, 2,300-volt, three-phase, General Electric, horizontal, condensing steam turbines, operating at a speed of 3,600 revolutions per minute and a frequency of 60 cycles, space being left for two additional units. The exciters will consist of two continuous-current, 15-kilowatt, 125-volt, General Electric condensing turbines operating at a speed of 4,500 revolutions per minute.

The switchboard was purchased from the General Electric Co., and will have eight panels for the necessary connections and all necessary instruments including wattmeters, synchronism indicator and voltage regulator.

There are at present four feeder circuits radiating from the power house. One circuit goes to the Heaton mine, about 1¼ miles distant, where about 300 kilowatts in motors are installed; another runs in the opposite direction to the company's Navajo mine, where it has approximately 600 kilowatts in motors; the third circuit goes to the Bartlett mine, about 1½ miles away, where 200 kilowatts in motors are installed; the fourth circuit goes to the town of Gallup, 5 or 6 miles away, where the electricity will be used for lighting and power. A voltage of 6,600 will be used for transmission as some of the developments are 4 to 6 miles from the plant. All the circuits are protected by General Electric aluminum cell lightning arresters. The necessary transformers and motors for use at the various plants for hoisting, pumping, and driving fans, have also been ordered.

WASHED HIS HOME FOR GOLD

The *Cape Town Argus* says a man named Whalen bought a few acres of ground near Ballarat with his wife's savings. From the mud and gravel of a sluggish spring he made sun-dried bricks and built a cabin, in which he started a bar for miners. Quite contrary to their usual habits, a colony of Chinamen commenced to visit his bar every night. Then Mrs. Whalen discovered that some one had, bit by bit, carried off the mud pigstye and its surrounding wall so gradually that it had almost gone before she noticed it. Soon the chimney and the cabin walls also began to vanish. After a careful watch Mrs. Whalen discovered that while one band of Chinamen kept her husband busy in the bar another band was stealing the chimneys and walls.

Whalen, acting on his wife's suggestion, also "stole a pan of dirt" from his own chimney and washed it. Then he ordered tents to live in and washed away the entire house. It was literally built of gold bricks. After that the pool and the spring were also attacked, and the result was a big fortune for the Irishman and his cute little wife.

LESSONS FROM THE PRICE-PANCOAST FIRE

THOSE who follow coal mining have undoubtedly noticed after each mine disaster that some one in commenting on the means of escape will say had the men taken such and such route they might have escaped. In a few instances men who took roundabout routes have gotten out, and then the public wonders why all did not follow their example. Of the possible reasons that might be advanced to explain this apparent neglect on the part of the dead in the recent Price-Pancoast fire three are cited because of their prominence and are:

That the men evidently were unacquainted with the mine and the second means of exit.

That too much dependence was placed by miners on the mine management; and

That the expression "All over" was not sufficient to warn men of impending danger.

During the excitement over the deaths of the 73 men in the Pancoast mine the impression prevailed that there was but one exit from the China bed, the public in the meantime overlooking the fact that those who escaped did so through a second exit. It would seem therefore that the men who perished did not know the way out of the mine through the other openings; and this is so evident to mine managers that two large coal companies are placing signboards in their mines on which are painted arrows pointing to the way of exit. One of the first things a wise man does when the goes to work in a strange place is to learn his way about; and if this be wise on the surface, it would seem to be infinitely more so in a mine. While the use of signboards is commendable, assume that the men's lights are out, which of course precludes any observation of the arrow, and this immediately suggests some token that can be made use of in the dark; however, the best guide post is a good general knowledge of the mine. John Gall with his knowledge of the Pancoast mine was able to lead 15 men through the dark to safety, and it is suggested that at least once a week the miners in a body be led through the various ways of escape; in fact, given a sort of fire drill.

One clause in the verdict of the Pancoast coroner's jury is the statement that "too much attention was given to fighting the fire and not enough to getting the men out." While this was uncalled for, in the face of the abundant evidence produced to show that the men were warned in time, nevertheless it suggests that miners place too much reliance on the mine management caring for them. In this particular case some men who escaped were warned twice to leave, one man who left immediately on being warned went home and did not learn of the seriousness of the fire until late that afternoon when he read the newspaper account. There is no doubt but that a considerable period elapsed between the time wood smoke from the fire was wafted through the mine and the time the cars caught fire, which makes it evident that the men placed too much

dependence on the mine management and failed to make use of nature's warning. That the men rely on the judgment of the mine officials should show the public that the latter are using every known precaution to protect those under them; nevertheless the miners should use their heads and not rely on any one for protection.

Once at least previous to the Pancoast fire the phrase "*all over*" (meaning no more work for the day) has led to loss of life because men did not take it as a warning. As an instance at the Pancoast mine, one miner who escaped heard the first cry of "all over," but having two cars proposed to load them before leaving the mine. The second alarm which was couched in proper language caused him to hustle from the danger zone.

Whenever there is any reason to call men out of the mine because of impending danger, "all over" should be omitted and some danger signal substituted.

CONVICT LABOR IN ALABAMA COAL MINES

THE editorial entitled "Legalized Slavery," which appeared in our issue January, was one that was not based on fact. It was not, however, inspired by intention of misstatement on the part of the editor. He was misled by a misrepresentation in connection with a test case involving the contract labor law of Alabama recently decided by the United States Supreme Court, and the methods and rate of payment for the work of the convicts.

The statement that no white men are working as convict miners was untrue, because about 10 per cent. of such convicts are white. This seems a small proportion, but it must be remembered that in that class of population in Alabama from which criminals come the negro race largely outnumbers the white race. The statement that the convict labor law was enacted to ensnare negro laborers through a scheme of forcing ignorant negroes to enter into a labor contract, and then for some alleged violation of the contract drag him into court and have him convicted of a misdemeanor to be punished by hard labor and a long sentence, is at variance with facts. Out of 1,350 convicts working in the mines of Alabama on January 1, the records show that but 10 were convicted of violation of labor contracts, and two of these 10 were charged with other misdemeanors as well.

The statement that the laws of Alabama require the operator to pay the miner $1 per ton for coal mined is so ridiculous that we feel humiliated that it should appear in our columns. No state in the Union fixes the price of mining by legal statute. The price is fixed by agreement, and, as in other states, it is regulated by the law of supply and demand.

The statement that ignorant men from farms are sent into gaseous mines, and whipped if they do not dig their allotment of coal, and that they are shot if they attempt to escape, is also at variance with facts.

At the various mines where convicts are worked, from 50 per cent. to 75 per cent. are actually doing hand mining. The balance are running mining machines, mine locomotives, firing boilers, working around the tipples, or in the blacksmith shop, or such other labor inside and outside the mines as they are capable of performing. A considerable number work in the gardens which produce the vegetables on which the convicts are fed. They all work exactly the same number of hours per day as do free workingmen. All extra work, such as work on Sundays, overtime, or work on holidays is optional with the convicts, and they are paid for it in cash at the same rate as free labor, less the cost of maintenance. The money thus earned is paid them on each regular pay day and may be sent by the men to their families and disposed of in any proper manner. It is stated that of the 1,350 convicts working in and about the mines on January 1 of this year, about 67 per cent. earned extra money, and this extra money for the month of January amounted to about $4,100, or an average of $4.60 per man. The convicts who are mining coal or operating mining machines are given a certain task to do, based on their physical condition. This task is not fixed by the operator, but by the State Prison Physician. The men are divided into four physical classes, and their tasks are fixed according to their classification. Every few months the State Physician reduces the men's classification for the purpose of breaking the monotony of the regular task.

There is a physician in constant attendance at the prison, and, if from sickness or any other cause a convict is not in proper shape for work in the morning, he can, by applying to the physician, be excused from work or his task reduced.

There are well equipped hospitals at all the prisons, the sleeping wards in the barracks are large, commodious, well ventilated, and very sanitary. Each convict is required to take a bath and put on clean clothing every evening as he comes from his work, and it is claimed that 90 per cent. of the convicts are in better physical condition when freed than they were when they were put in prison.

Very little corporal punishment is necessary, and when it is inflicted it is on very vicious and unruly fellows. The statement that they are shot if they attempt to escape is true in the same sense as would be a similar statement made regarding convicts in the Pennsylvania or New York penitentiaries.

The statement that some have tried to commit suicide, and that others have run the risk of being killed by the guards rather than endure their prison life needs but one comment. In every prison the world over, prisoners try to commit suicide and others take great risks in endeavoring to escape, no matter how lenient the prison regime may be.

The above information refutes completely the mis-

statements in our January issue, and we cheerfully publish them as an act of justice to the state of Alabama and the operators of the coal mines in that state.

Having done this we have a perfect right to condemn the convict labor practice of Alabama on fair and rational grounds. In doing this we do not feel that the operators who employ such labor are the persons to blame. They need labor and if they did not use this cheap labor their competitors would. The fault is with the people of Alabama as represented in their Executive and Legislature.

There is no question but that convicts should be made to work, and at least earn their keep and the expense of maintaining the penal institutions, if the products of their labor do not enter into competition with those of free labor. We do not believe that they should be employed as coal workers as they are in Alabama. Their employment as such necessarily keeps out of the mines just that number of free men, both black and white. Besides, the practice is one in which if the prison contractor and mine owner happen to be unscrupulous, there is room for very grave abuses affecting not only the convicts, but the owners and employes of mines employing free labor only. The writer has always held the opinion that every convict should be made to work for two reasons. One for the salutary effect of occupation on the mind, and the other because the majority of convicts are such because of their abhorrence of honest labor, and to make them earn at least a part of their keep does them good in a corrective way.

There is a kind of work they can do, and it is work that interferes least with free labor. They can crack stone in the jail or prison yards, and this cracked stone can be effectually used to make, repair, and keep in order the public roads. It is true stone crushers can do this cheaper than it can be done by hand, but the hands that are employed when convicts do it, cost nothing but their keep, and this is usually as cheap as it can be made consistent with health and sanitation. If each state would put its prisoners to such use, it would materially reduce the just complaints against our abominable roads; and, besides, the privileges and rights of free honest labor would be interfered with less than by any other work.

BOOK REVIEW

Guide to Technical Writing, by T. A. Rickard, editor of the *Mining Magazine*. Published by Mining and Scientific Press, San Francisco, Cal. The book contains 168 8mo pages embodying the criticisms, pleas, and suggestions of an earnest man for better mining and metallurgical writing. Several years ago Mr. Rickard sent the writer a pamphlet accompanied by a letter in which he suggested that uniformity in expression and style be adopted. The United States Printing Office, the United States Geological Survey, The International Textbook Co., and others, have adopted "style sheets" that contain rules for editors, writers, proof readers and printers, but this is not what Mr. Rickard had in mind, for an author could conform to the rules yet the subject matter be written poorly. A plea for "Greater Simplicity in the Language of Science" was another paper by Mr. Rickard and was read before the American Association for the Advancement of Science. By this time Mr. Rickard had come to the conclusion that to disseminate mining and metallurgical information where it would do the most good, the literature must be stripped of pedantry. He commenced by telling the pedants, in the parlancy of Wall Street, that while they were long on orthography and etymology, they were short on syntax. While Mr. Rickard's criticisms pointed out the idiosyncrasy in others, they were not always received in the right spirit, for which reason he made a few enemies and a host of friends. Being in sympathy with Mr. Rickard, it is difficult to criticise his "Guide to Technical Writing," for when following the argument interestedly, carelessness like that on page 24, where *then* is used for *thus;* or "12 divided by 3 making 4 ft.; or Thus 8 by 12 in., not 8×12 inches" is apt to be overlooked. Again, some might differ with him on page 25 and write ten is accurate, 10 is exactly, 10.0 is accurate to tenths only. Probably no one has done more to eliminate superfluous words in technical writing than Mr. Rickard, nevertheless on page 62 he writes "So far so funny, but . . ." When writing on the use of titles, he has this statement "In America, it is chaos; the titles Professor and Doctor are employed so loosely that they are well-nigh meaningless." The criticism is that "if it be chaos" his sentence is just as fulsome without that phrase. Usually when an author trips in one paragraph, the critic finds two other stumbles, for example "Surgeons, veterinaries and dentists are denied the privilege," could have been written "The privilege is denied to surgeons, etc." without making use of a false passive. Mr. Rickard's paper on "Standardization of English in Technical Literature" fell like a bombshell among the Englishmen, who were using dreadful words in their writings. It made them gasp and exclaim "Whatever manner of man is he." Read his "Guide to Technical Writing"; hit him in the back when he is looking at you and you will ascertain as the *Canadian Engineer* remarked, that "His pen has a sting so sharp as a serpent's tooth." The intent of the author on Technical Writing was to benefit the mining and metallurgical professions, and this he has accomplished to a greater extent than he is aware. Mr. Rickard's writing is not above criticism; he does not profess to be a hierophant; he is always fair and open to conviction; and does not use his time in useless fault finding.

When *one* is above criticism *one* lacks initiative and becomes what this American thinks an Englishman means when he speaks of another Englishman as a "Rotter."

Tables for the Determination of Minerals is the name of a new book published by the McGraw-Hill Book Co. The price is $2. By means of these tables Prof. E. H. Kraus, and his assistant, W. F. Hunt, A. M., of the University of Michigan, propose to determine 250 minerals by means of their physical properties, occurrences, and associates.

It is difficult to determine minerals by means of physical tests with blowpipe tests for confirmation and vice versa. This the authors seem to realize, for they refer each mineral to one of three standard mineralogies. The authors state that the fundamental basis of these tables depends on luster and color, further subdivisions being introduced by the streak and hardness. We have frequently known of eminent mineralogists making snap determinations of minerals by their appearance, and being caught, but when something depends on it, the blowpipe and wet tests are requisitioned, therefore, why have two or three books where one must be owned. It is difficult for one to determine microline from orthoclase, or pyrite from marcasite, by the use of tables alone, and when it comes to minerals like columbite, wolframite, chromite and others having similar appearance, physical tests alone are not sufficient.

The Thirty-Eighth Annual Edition of The Coal Trade has just been issued by F. E. Seward, for 42 years the editor

and proprietor of *The Coal Trade Journal*, the oldest newspaper in the United States entirely devoted to the interests of the coal trade. The 1911 edition of his annual review of the trade comprises 192 pages, well printed and substantially bound. An index embracing some 600 lines of type indicates how numerous are the subjects covered and how great a mass of information is gathered together in the compactly arranged pages of the volume before us. The book is published by F. E. Seward, 20 Vesey St., New York City. Price $1.50.

BOOKS RECEIVED

United States Geological Survey Publications, Washington, D. C. Bulletin No. 431-B, Advance Chapter From Contributions to Economic Geology for 1909, Part II, Mineral Fuels, Coal and Lignite, by Charles Butts, M. R. Campbell, E. G. Woodruff, C. T. Lupton, J. S. Diller, M. A. Pishel, H. E. Gregory, and A. C. Veatch; Bulletin No. 447, Mineral Resources of Johnstown, Pa., and Vicinity, by W. C. Phalen and Lawrence Martin. This will be found of interest to coal miners. Bulletin No. 465, The State Geological Surveys of the United States, by C. W. Hayes; Production of Asbestos in 1910, by J. S. Diller; The Production of Gold and Silver in 1909, by H. D. McCaskey; The Manufacture of Coke in 1909, by Edward W. Parker; The Production of Monazite in 1910, by Douglas B. Sterrett; Zinc and Cadmium in 1909, Smelter Production, by C. E. Siebenthal; The Production of Coal in 1909, by Edward W. Parker; Water-Supply Paper 257, Well-Drilling Methods, by Isaiah Bowman; Water-Supply Paper 258, Underground Water Papers, 1910, by M. L. Fuller, F. G. Clapp, G. C. Matson, Samuel Sanford, and H. C. Wolff; Geologic Atlas of the United States, Sewickley Folio No. 176, Pennsylvania, by M. J. Munn.

Bureau of Mines, Washington, D. C., Miners' Circular No. 3, Coal-Dust Explosions, by George S. Rice; Bulletin No. 7, Essential Factors in the Formation of Producer Gas, by J. K. Clement, L. H. Adams, and C. N. Haskins.

Department of Mines, Mines Branch, Eugene Haanel, Director, Ottawa, Can., Preliminary Report on the Mineral Production of Canada for 1910, by John McLeish, B. A.; Chrysotile-Asbestos, Its Occurrence, Exploitation, Milling, and Uses, by Fritz Cirkel, M. E.

The Mineral Industries of Canada, by H. Mortimer-Lamb, Secretary, Canadian Mining Institute, Montreal, Can.

Mineral Production of Ontario for 1910, Bulletin No. 7, The Bureau of Mines, Hon. F. Cochrane, Toronto, Can.

Contributions to the Economic Geology of the Republic of Argentina, by Dr. Richard Stappenbeck, of the Division of Mines of Geology and Hydrology, Ing. E. Hermitte, Chief of the Division, Buenos Aires, Argentine Republic.

Proceedings and Collections of the Wyoming Historical and Geological Society, Volume XI, Wilkes-Barre, Pa. The price of this book is $3.

Report of the State Bureau of Mines of Colorado for the Years 1909 and 1910, by T. J. Dalzell Comissioner of Mines, Denver, Colo.

South Dakota School of Mines, Bulletin No. 9, The Badland Formations of the Black Hills Region, by Cleophas C. O'Harra, Rapid City, South Dakota.

Register of the School of Mines of New Mexico for 1910 and 1911, Socorro, N. Mex.

United States Geological Survey, Washington, D. C., Chart of the Mineral Products of the United States for the Calendar Years of 1900 to 1909.

Tennessee State Geological Survey, Nashville, Tenn., Bibliography of Tennessee Geology, Soils, Drainage, Forestry, Etc., by Elizabeth Cockrill; Bulletin No. 4, Administrative Report of State Geological Survey for 1910, by George H. Ashley, State Geologist; Bulletin No. 10-A, Preliminary Study of Forest Conditions in Tennessee, by R. Clifford Hall.

North Carolina Geological and Economic Survey, Joseph Hyde Pratt, State Geologist, Chapel Hill, N. C., Bulletin No. 22, Cid Mining District, of Davidson County, N. C., by Joseph E. Pogue.

Geological Survey of Ohio, J. A. Bownocker, State Geologist, Columbus, Ohio, Fourth Series, Bulletin No. 12, The Bremen Oil Field; Fourth Series, Bulletin No. 11, The Manufacture of Roofing Tiles, by Worcester & Orton.

A Geographical Report on the Franz Josef Glacier, by James MacKintosh Bell, Director, New Zealand Geological Survey, Wellington, New Zealand.

Review of the Joplin District Folio; Highway Construction; Sleet Storm in the Ozark Region of Missouri; Lead and Zinc Mining in the Central States; The Origin of the Lead and Zinc Deposits of Southwestern Missouri; Zinc and Lead Deposits of the Upper Mississippi Valley; Genesis of the Lead and Zinc Ores of the Mississippi Valley, by E. R. Buckley, Ph. D., State Geologist, Rolla, Mo.

Annual Report of the Government Mining Engineer for the Year ending June 30, 1910, Transvaal Mines Department, H. Warrington Smyth, Secretary, Pretoria, South Africa.

Report of the Superintendent of the Coast and Geodetic Survey for 1910, Hon. Charles Nagel, Secretary of Commerce and Labor, Washington, D. C.

RULES FOR HANDLING KANITE

The kanite generally remains loose in the cartridge for any length of time. However, if a cartridge be found packed too tightly, it should be rolled or kneaded between the hands for a few moments until the kanite becomes loose. This operation is absolutely safe and allows the cap or electric fuse to be easily inserted.

The cap or fuse is inserted in a kanite cartridge when loose by turning the cartridge with left hand, at the same time squeezing the top end with two fingers of this hand, while the right hand lightly and easily pushes the cap into the cartridge.

Kanite should be kept in as dry a place as possible. Do not allow packages or cartridge to remain open. This precaution is simply that which has to be followed with any other powder.

The caps are electrical detonators recommended as of greater strength than the so-called double-strength caps.

For placing fuse in cap or in adjusting electrical fuses, the general instructions applied to dynamite can be followed. Either one or the other of the fuses should be imbedded entirely in the explosive and at the top end of the top cartridge.

Kanite is absolutely safe to handle; but after the insertion of the cap the cartridge must be handled with care, not on account of the kanite, but on account of the cap. Kanite should not be stored in contact with the caps or exploders.

When kanite cartridges are placed in a drill hole they should be pressed lightly together. In tamping, after the hole is loaded the first tamping of loose clay, earth, or dummies of same, upon the explosive should be done lightly for a few inches, then tamped in degrees tighter and tighter throughout the remainder of the length of the bore hole. The upper part of the tamping should be as tight and hard as possible to gain the best results of blast.

In calculating a charge of kanite in comparison with 40 or 60 per cent. dynamite and black powder, the weight of kanite should equal the weight of the dynamite and one-fourth the weight of black powder.

In comparison with dynamite only, the weight of kanite should equal the weight of dynamite.

In comparison with black powder the weight of kanite should be one-fourth of the weight of black powder.

This comparison is for the first shot only. By gradually reducing the weight of kanite in each succeeding shot the miner will readily ascertain for himself the proper weight to do the most satisfactory work.

CORRESPONDENCE

Filter Presses

Editor Mines and Minerals:

SIR:—On page 597, of the May issue of MINES AND MINERALS, was published an article by Percy E. Barbour, entitled "Developments in Cyanide Practice." From this article I quote the following:

"Today, five years later, still there is only one wholly filter-press plant of any size in the country and it is unlikely that it would be duplicated if any increased capacity were desired, although the working costs are satisfactory."

I presume the plant above mentioned is the Homestake slime plant, where 1,600 tons are treated daily, as this is the largest slime plant using filter presses.

Mr. Barbour is certainly correct in saying that costs were satisfactory, but might have gone further and said that the working costs at this plant are the lowest in the world. As to its duplication being unlikely, in case of increased capacity, it would rather seem as if Mr. Merrill, the president of this company, and the designer of the plant in question, who still retains the position of consulting metallurgist for the Homestake company, should be equally as well informed as Mr. Barbour, and this statement is certainly news to him. In fact, the plant is being continuously enlarged and a greater proportion of Homestake tailings treated therein. As to its being the only wholly filter-press plant in the country, I would suggest that Mr. Barbour visit the Esperanza, at El Oro, Mex., where he will find that two 90-frame and three 76-frame Merrill presses, have been working for an extended period treating 700 tons per day and with operating costs exceptionally low even for this district.

Moreover, he will find here increased capacity being installed including a sixth Merrill press of 90 frames.

If Mr. Barbour lives in the West, instead of going so far as Esperanza, he need only go to Blair, Nev., and watch three Merrill filter presses at the Pittsburg Silver Peak mill, treating 480 tons per day of a very talcose slime, again with operating costs considerably below any other installations operating under like conditions.

If anything further were needed to show that Mr. Barbour's statement is misleading, it will be found in the following list of orders for filter presses placed with this company in the last year:

Name	Number of Presses	Number of Leaves
Compania Beneficiadora de Pachuca (Santa Gertrudis)	4	360
New York and Honduras Rosario Mining Co.	2	180
Dome Mines Syndicate	2	152
Motherlode Sheep Creek Mining Co.	2	70
Palmarejo Mining Co.	3	270
San Luis Mining Co.	1	35
Portland Gold Mining Co.	2	152

It will be noted that this totals 16 units containing 1,219 leaves distributed over seven companies operating in Canada, the United States, Mexico, and Central America. The approximate tonnage of the above per day is about 2,100 tons.

Evidently filter pressing is not quite as dead as Mr. Barbour would have us believe.

C. C. BROADWATER, Vice-President,
Merrill Metallurgical Co.

Determination of Meridian

Editor Mines and Minerals:

SIR:—I have read with interest and profit the articles in MINES AND MINERALS on the determination of the meridian, by the single altitude method, from an observation of the sun. I introduced the method into this section some 7 or 8 years ago and have used no other for many years. I have used almost every formula that has been suggested, but have used the McElroy formula since it came to my notice. I have modified this formula, however, so as to eliminate the use of the table of natural functions, which seems to me a decided advantage.

The general formula for the solution of the spherical triangle is:

$$\cos a = \cos b \cos c + \sin b \sin c \cos A \qquad (1)$$

In the particular triangle we have to solve

$a = 90° -$ declination
$b = 90° -$ altitude
$c = 90° -$ latitude, and
$A = Z$, or azimuth

which, substituted in (1) converts that equation into

$$\sin d = \sin a \sin l + \cos a \cos l \cos Z \qquad (2)$$

whence,

$$\cos Z = \frac{\sin d - \sin a \sin l}{\cos a \cos l} \qquad (3)$$

which is McElroy's formula, although not in its ultimate form, and in which

$a =$ altitude
$b =$ latitude, and
$d =$ declination

If, now, in order to adapt this formula to logarithms, we let

$$\tan m = \frac{\sin a \sin l}{\cos d} \qquad (4)$$

and substitute this in (3), we shall obtain

$$\cos Z = \frac{\sin d \cos m - \cos d \sin m}{\cos a \cos l \cos m},$$

or

$$\cos Z = \frac{\sin (d-m)}{\cos a \cos l \cos m} \qquad (5)$$

Formulas (4) and (5) solve the problem and permit the use of logarithms. It is to be observed that when the declination is south, $d-m$ becomes $d+m$.

The writer uses printed blanks in a loose-leaf binder and has no difficulty in calculating the azimuth in a few minutes in the field. An example is given herewith, showing the features of the printed blanks and the manner of making the calculation. The sines and cosines are taken out at one opening of the tables and written in their respective places for both formulas. The angle m and its cosine are taken out together and then the sine of $d-m$. The negative and positive quantities are added directly, which saves time, and the problem is solved.

HENRY O. HIPPER

Ocampo, Chihuahua, Mex.

Rolling Friction

Editor Mines and Minerals:

SIR:—Some people maintain that the resistance due to rolling friction of mine cars is greater in summer than in winter. In the catalog of a large locomotive concern is this sentence: "The resistance is greater in winter." Will you kindly state which is correct and give reasons? W. C. A.

THE CHEMIST'S PLACE IN MINING

The watchword of modern industry is no longer "increased production" alone, it has changed to "increased efficiency of production." The day of cheap raw material is passing, if indeed it has not already gone, and the mining industry faces a new set of conditions. Nowhere more than in the production and transmission of power are there greater opportunities for improvement—for the saving of time, and labor, and money. That the chemist ought to take the foremost part in solving the problems of power efficiency is the argument convincingly set forth in a paper read before the American Chemical Society by Arthur D. Little, of Boston. Mr. Little makes a vigorous presentation of the chemist's special qualifications for dealing with questions of energy, and urges a stand against the customary monopolizing of power problems by the mechanical engineer.

Chemists forget that their science deals with energy no less than with matter, and that in fact chemistry as a science began with the recognition of the principles, materials, and products of combustion. They have allowed the mechanical engineer to usurp many things which properly come much more directly within their own province.

The combustion of coal is a typical chemical process. The selection of the most efficient coal and the determination of the conditions necessary for its most efficient combustion are essentially chemical problems. Chemical problems also are those arising in the manufacture of producer and illuminating gas, their utilization in gas engines, the development of power from the waste gases of the blast furnace, the adaptation of conditions to the proper handling and burning of lignite and waste coal, the thermometric exploration of coal piles to forestall spontaneous combustion, smoke abatement, the control and improvement of fireroom conditions by draft regulation, flue-gas analysis, temperature measurements, and even the placing of firemen on the bonus basis. Taking power plant practice and the conditions of coal purchase as they stand, the properly equipped chemist should be able to increase the efficiency of power production from 5 to 30 per cent.

The analysis of boiler compounds as an end in itself presents little to excite enthusiasm, but when such analyses are made the means of saving $3,600 a year in the power plants of a single company they take on a new and larger aspect, not only in the mind of the chemist, but in the mind of the chemist's client.

The chemist who attacks the problems of power production will not hesitate to go outside the laboratory and take his property wherever he finds it. He will conduct boiler and engine tests, study the efficiency of grates and stokers, familiarize himself with the marvelous promise of the low-pressure turbine as an agent in efficient power production. While straining every resource of his science to produce steam economically by the combustion of coal, is it common sense for the chemist to stop there in ignorance of the fact that the efficiency of that steam can be increased at once from 25 to 100 per cent. by coupling a turbine to the exhaust?

The distribution of power supplies problems no less directly within the province of the industrial chemist. He may begin with the analysis of lubricating oils. He proves his own inefficiency if he stops there. He must inform himself regarding the market prices of oils used elsewhere for similar service, the adaptability of the oils in question to application to the bearing by soaked waste, sight feeds, or gravity cups. He must be prepared to interpret his analysis in terms of practice, and to follow the oil through the plant in order to prescribe conditions which shall keep down waste. There are few plants in which the industrial chemist working along legitimate lines cannot save from 20 to 60 per cent. of the entire lubrication account, while the oil analyst has to his credit merely a few figures which his client probably fails to understand.

The efficiency and life of bearing metals varies over an extraordinarily wide range. Some are merely the refuse from type foundries, others are so carefully adapted in their composition to the requirements of particular service as to show an efficiency 15 times or more as great as that of inferior material. Here again the mere analysis means little, the practical question is "Which is the more efficient metal under the conditions imposed by practice?"

Much additional might be said regarding the opportunity before the chemist when any material concerned in power transmission is the subject of his study, whether it be leather, rubber, or canvas belting, belt dressing, insulating material, trolley wire, trolley cars, or trolley wheels. In every case it is within his power to create new standards of efficiency.

The chemist is one of the most efficient arms of ore mining and metallurgy, although his field of activities has been narrowed in these industries by his engineering deficiencies and office routine; in fact his specializing process of hibernation prevents his boarding and climbing the fence to his natural field of endeavor.

DISASTROUS AIR EXPLOSIONS

Violent explosions have on several occasions occurred in air compressors on the Rand, fume and poisonous gases descending the air mains to the workmen below with calamitous results; on one such occasion over 100 men were "gassed," some of them fatally. These explosions, which also occur in other mining fields, are brought about in the air cylinders of compressors as the result of carelessness, the use of too much oil, or poor qualities of oil, for lubrication in the cylinders, or defective or leaking delivery valves. Any of these may cause the cylinder lubricating oil to char and the resulting gases to ignite and explode. Very little lubricating oil is needed in the air cylinders—less than in a steam cylinder; good oil in small quantities should be used; an excess of oil only results in the ports and valves being obstructed by a deposit of carbon, and this is apt to bring about a high temperature. Air cylinders may be cleaned by soft soap and water; kerosene and similar inflammable oils should never be used for this purpose. A thin oil, with very little carbon in it, and with a high flash point is the best lubricant for the air cylinder. The explosions in compressors frequently arise from the breaking or sticking of the air-discharge valve, which results in some of the hot compressed air returning to the cylinder, and the additional heat given to this air by the recompression is such as to exceed the flash and ignition point of the oil present, which, therefore, vaporizes and explodes. The ports and valves of compressors should be periodically inspected if accidents are to be avoided.

SCIENTIFIC STUDY OF COPPER DEPOSITS

Written for Mines and Minerals, by A. J. Sale

The Application of Such Information as May Be Obtained from Sampling and Assaying

If an article on this subject were to be complete and involve all considerations and geological features it would fill a whole volume. Such points as the difference between silicified, leached and oxidized monzonite and their twin sisters in the limes, that is, silicified, altered and ferruginous jasperoid; the effect of water level upon oxidization; the difference between kaolinized lime and highly altered rhyolite; the age of rhyolite surface flows; the action of faulting upon deposits; causes of copper deposition: the probable formation of secondary iron pyrites; the action of jasperoid; and hundreds of other geological, lithological, and mineralogical features are of extreme importance in the study of large secondary copper deposits. But in this article I will confine myself to the application of only such information as can be furnished by any assayer. The principal auxiliary in using this information is ordinary coordinate paper.

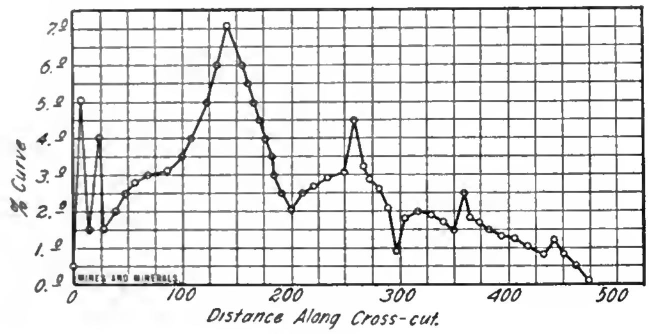

Fig. 1

The first chart that I have found of value, where an ore body is partly blocked out by drifts and cross-cuts, is made by plotting the spacing of the copper assays along the abscissa of the paper and the assays up the ordinates. The paper used for this purpose is a coordinate tracing paper of the same scale of abscissa spacing as the assay maps of the mine. For then the paper can be laid directly on the map and the spacing of the assays obtained without scaling. One inch to 1 per cent. copper is a convenient scale for the ordinates. Fig. 1 shows a typical chart of a cross-cut. A chart of this type is of special advantage where the assays were taken as breast samples and the spacing irregular. I am of the opinion that if a smooth curve were sketched in as a compromise curve to the irregular chart, the errors of sampling will be considerably eliminated; for the spacing can then be taken uniformly along the abscissa and the compromise assay at any point taken from the chart, from which the exact mean assay of the cross-cut or drift can be figured. These charts can be used to determine whether any heading is a drift or a cross-cut. A true drift, which is driven parallel to the axis of the ore body, will have comparatively uniform assays and will show in the chart as a straight line parallel to the abscissa, while headings which are driven at an angle to the axis of the ore body will approach more nearly to the typical form as they approach a condition of true cross-cut, that is, perpendicular to the axis of the ore body. Where the chart is very jagged, the gangue material is usually clay or talc and the copper mostly contained as chalcopyrite. Where any one point is very much higher or lower than the normal, there are probably errors in sampling which should be checked if possible.

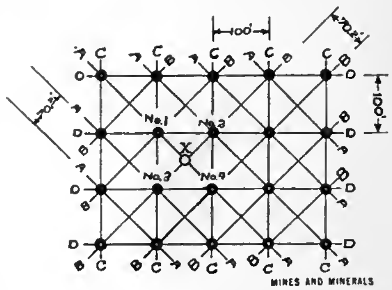

Fig. 2

Where churn drills are used to block out a deposit, the best information is obtained where the holes are drilled at the corners of blocks, usually one or two hundred feet spacing. In studying the results from churn drills, I consider that more accurate results can be obtained from the diagonal cross-sections (*AA* Fig. 2) and diagonal longitudinal sections (*BB*) than from the normal cross-sections (*CC*) and normal longitudinal sections (*DD*). For while the spacing between the holes will be $\sqrt{2} = 1.414$ times as far as the normal sections, the spacing between the sections will only be $\frac{1}{2}\sqrt{2} = .707$ times as far. It is probable that more accurate calculations can be obtained where the spacing between the sections is a minimum. Also the actual conditions can be judged more accurately. In Fig. 3 the ore is assumed to be in a position as shown between hole No. 1 and hole No. 3, and there is no check on this assumption. In Fig. 4 the ore is assumed to be in the position as shown between hole No. 2 and hole No. 3. Assume a hypothetical hole *X* to be drilled midway between holes No. 2 and No. 3. In Fig. 5 the ore is assumed to be in the form which appears most logical. In this figure draw in *X* between holes No. 2 and No. 3. From Fig. 2 it is seen that this should show the same conditions as *X* in Fig. 4. If so all assumptions are probably correct; if not, some other consideration may determine which *X* is nearest to the true condition; after which it can be used as a valuable auxiliary.

Having completely drilled an ore body and made the sections, several important points must be considered before final calculations can be made. The first is that only $\frac{7}{10}$ of any copper assay can be recovered in the mill. Consequently the sections should be readjusted with a new set of assays, each of which is $\frac{7}{10}$ of the assay obtained from the assayer. The next important question is—What is the minimum net assay of copper that can be considered ore? This will be a variable limit according to the price of the metal and many other conditions. It is best to outline the sections to fit the condition of variable minimums of 1.0, 1.5, 2.0, 2.5, and 3.0 per cent. If there are more or less mine workings in connection with the drilling, much assistance can be obtained by the study of "isochemic lines." This is a term that I have taken the liberty of inventing to mean lines of equal chemistry or net copper

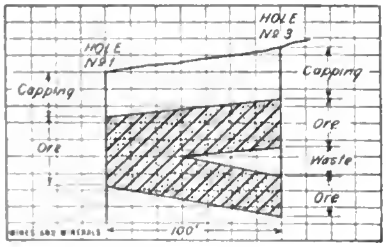

Fig. 3

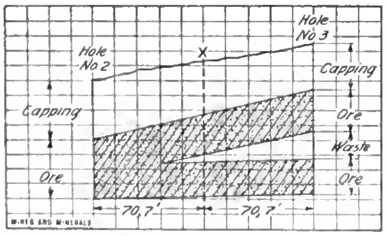

Fig. 4

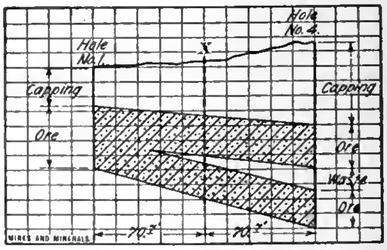

Fig. 5

assay. Fig. 6 shows the application of these lines to a mine map. Fig. 7 shows how the lines in Fig. 6 are used to assist in outlining a drill section for minimums of 2 and 3 per cent. Having outlined each set of sections for variable conditions of minimum the areas can be figured from geometric figures or by a planimeter.

The spacing of the holes being uniform, and the concentration loss adjusted, the net mean grade for any section is probably best obtained by taking the sum of the multiples of the number of feet of ore in each hole by the net mean grade for this number of feet and dividing by the total number of feet of ore in all of the holes.

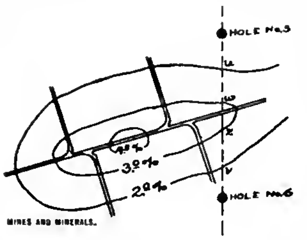

FIG. 6

Having properly adjusted each section, the next thing to do is to study them collectively. Each percentage minimum should be figured separately. In studying the sections collectively, simple isogonic projections are very useful. These are made by assuming that the area of each section lies in a square. Fig. 8 shows how one of these projections is made. If the spacing of the drill holes is 100 feet, and the projection is made from diagonal sections, the distance between the sections will be $\frac{1}{2}\sqrt{2}\times 100 = 70.7$ feet. Suppose that the isogonic projection is to be made to the scale of 1 inch 100 feet. Start with the line AB (Fig. 8) and draw a vertical line every .7 of an inch. Now, since the projection is to be made to the scale of 1 inch to 100 feet, a section 1 inch square will represent 10,000 square feet of area. That is, $h=1$ inch for a sectional area of 10,000 square feet. And, since the area of each section is assumed to lie in a square, each area will be proportional to the square of its h, or h for any area can be found from the formula $h=\sqrt{\frac{\text{area}}{10,000}}$. Having plotted h for each section, the isogonic projection can be drawn in various ways, according to the assumed point of vision. A convenient method is to draw through the top and bottom of each h a line making an angle of 30 degrees with the horizontal. Along each of these lines a distance of one-quarter of its corresponding h is laid off in each direction and the projection completed as shown in Fig. 8. It is probably best to use the prismoidal formula to figure the volume of each segment.

Having figured the volume for any minimum percentage, the tonnage can be obtained by dividing the volume by the number of cubic feet of rock in place to the ton (probably 12 to 15). The final mean grade is probably best obtained by taking the sum of the multiples of each area by its mean grade and dividing by the sum of the areas. The loss of concentration having been compensated for, this will be a net mean grade. We now have a series of tonnages and mean grades figured for 1, 1.5, 2, 2.5, and 3 per cent. minimum of net copper extracted. Suppose it becomes important to know figures for such minimums as 1.3 per cent. or 2.25 per cent. or any other figure not ending in .0 or .5 per cent. This can readily be obtained from a chart of variable minimums. Fig. 9 shows how such a chart is made. The minimum percentages involved are plotted along the abscissa and the results up the ordinates. Any convenient scale can be used. The points on the curve of net production for each figured minimum are obtained by multiplying the corresponding points of tonnage and net mean grade and the product by 20; for each net per cent. is equivalent to 20 pounds of copper recovered per ton of ore. If the chart is correctly made, any intermediate point on the curve of net production will be equal to the corresponding point on the curve of tonnage, times the corresponding point on the curve of net mean grade, times 20. It is seen that a chart of this type furnishes the information for determining the tonnage, net grade, and total net recovery for any percentage.

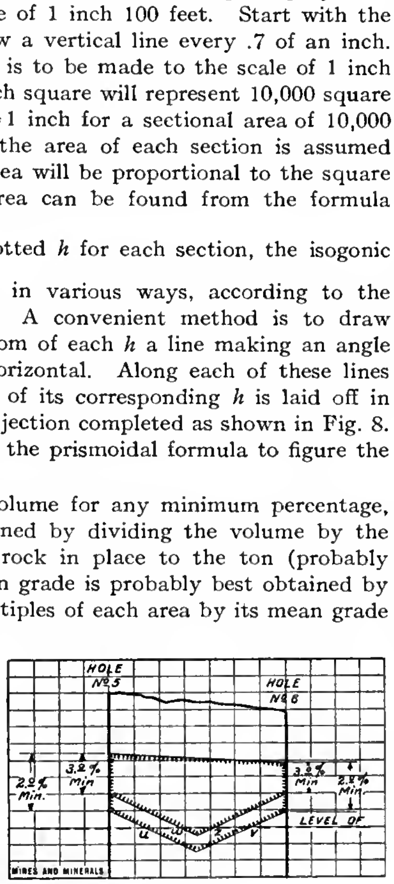

FIG. 7

Having completely figured an ore body for any assumed minimum of recovery, it is usually desirable to show at a glance how the ore body looks in the ground. A very simple and convenient preliminary model can be made by simply tracing any set of cross or diagonal sections on glass plates and setting them vertically in a wooden frame at a scaled spacing proportionate to the distance of the sections apart and at a uniform base of elevation. A more complicated and probably more useful model, where the ore body has been completely drilled, is made by drawing a set of contour lines for the ore body and tracing them, along with the topographical contours, on glass plates which are placed horizontally in a frame at a distance apart proportionate to the distance between contours.

The final information that can be obtained for an ore body is what is to be expected in the smelter. The actual iron analysis will be of little value as there is usually more or less ferrous or ferric oxide in the gangue as well as the concentrate. The net copper, sulphur, and magnetite are the important features. Sulphates should be removed before the sulphur analyses are made. Probably 85 per cent. will be a reasonable estimate of the amount of sulphur, that will go into the concentrate, as the loss of pyrite should not be as great as of chalcocite.

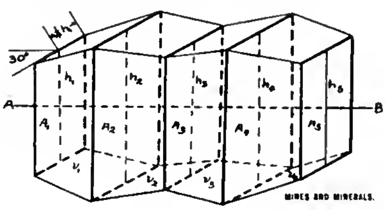

FIG. 8

The magnetite is removed with a magnet and weighed as such. Eighty per cent. will probably be a fair estimate of what goes into the concentrate. Gold and silver should be estimated at from 50 to 70 per cent. of their mean assays, according to the condition in which they occur in the ore.

Assume that the final proportionate mean analysis of an ore body is: Copper, 2.61 per cent.; sulphur, 3.52 per cent.; magnetite, 1.32 per cent.; and gold, 41 cents; silver, .31 ounce.

Now, if the copper is contained as chalcocite along with pyrite, the formula of the concentrate, neglecting the magnetite, will be $Cu_2S+xFeS_2$. Let S' represent the sulphur contained as chalcocite, S'' the sulphur contained as pyrite, and S the total sulphur. Taking the automic weight of copper as 63, of iron as 56, and of sulphur as 32, the ratio $S' : Cu = 32 : 126$ or $S' = \frac{32}{126}\,Cu$ is obtained. Therefore $S - S' = S'' = S - \frac{32}{126}\,Cu$. Also $Fe : S'' = 56 : 64$ or $Fe = \frac{56}{64}S'' = \frac{56}{64}(S - \frac{32}{126}Cu) = \frac{7}{8}S - \frac{2}{9}Cu$. Therefore the iron required is seven-eighths of the sulphur minus two-ninths of the copper. For the above analyses $Fe = \frac{7}{8}\times 3.52 - \frac{2}{9}\times 2.61 = 2.50$ per cent.

The above analysis then becomes: Copper, 2.61 per cent.; sulphur, 3.52 per cent.; iron, 2.50 per cent.; magnetite, 1.32 per cent. Total, 9.95 per cent.

Dividing 9.95 into 100 we get practically 10. Therefore the ore will theoretically concentrate 10 : 1. This I call the theoretical concentration ratio. The theoretical concentrates will then be 10 times each respective analysis, or: Copper, 26.1 per cent.; sulphur, 35.2 per cent.; iron, 25.0 per cent.; magnetite, 13.2 per cent.

But magnetite is $\frac{21}{29}$ iron. Therefore the final theoretical concentrates will be: Copper, 26.10 per cent.; sulphur, 35.20 per cent.; iron, 34.56 per cent.; and gold, \$4.11; silver, 3.10 ounces.

The losses of concentration having been already compensated, the only probable difference between the theoretical

concentrates and the actual will be the amount of gangue (or silica) contained in the concentrate. If for the above analysis the concentrate is assumed to contain 20 per cent. SiO_2, all figures should be multiplied by $\frac{8}{10}$ and the actual concentrate would contain: Copper, 20.88 per cent.; sulphur, 28.16 per cent.; iron, 27.65 per cent.; silica, 20.00 per cent.; and gold, $3.27; silver, 2.48 ounces.

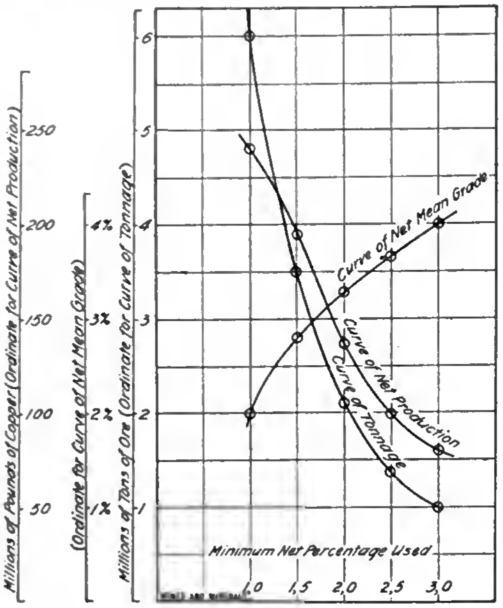

Fig. 9

The concentrate has been increased by one-quarter the weight of the theoretical at the expense of the gangue, therefore the actual concentration ratio will be $8\frac{3}{4} : 1\frac{1}{4}$ or 7 : 1.

IDAHO'S METAL PRODUCTION IN 1910

In his annual report for 1910, Mr. F. Cushing Moore, State Inspector of Mines for Idaho, complains that "very little progress has been made in the mining development of the state (Idaho) during the past year (1910), but the producing mines have maintained their output with a very few exceptions, and a few properties have been added to the producing list by having transportation facilities brought within commercial limits. This lack of progress in development has been caused by the apathy displayed by the investing public, due primarily to the depressed condition of the money market and the reflex action of former flotations and developments which have proven failures."

Notwithstanding the "skinee" for the time being refuses to return to the "skinner" to be further "skun," an increase of nearly 10 per cent. in the value of the metal production over that for the year 1909 indicates a healthy growth in a period of general financial depression, coming as it does mostly from the long established Cœur d'Alene district of Shoshone County.

The totals of metal production for the state are:

Gold, fine ounces	49,289.22	$ 1,018,808.20
Silver, fine ounces	7,890,388.00	4,268,813.00
Lead, pounds	239,144,570.00	10,761,057.70
Copper, pounds	5,837,639.00	753,055.40
Zinc, pounds	5,995,600.00	333,513.60
Grand total for 1910		$17,135,695.90
Grand total for 1909		15,606,862.15
Increase		$ 1,528,833.75

It will be noted that the individual items when totaled amount to $448 less than the sum given by Mr. Moore.

The production of Shoshone County, the Cœur d'Alene district, for 1909 was valued at $13,723,105 and for 1910 at $15,275,024.15, or approximately 90 per cent. of that of the entire state.

THE VALUE OF SURFACE TRENCHING

Written for Mines and Minerals

If the true anecdotes of all the mineral finds made by surface trenching could be collected, a volume would doubtless be the space required for their preservation. Certain Spokane operators, for instance, might relate how a Montana deposit was developed by a little trenching from a $50,000 gamble into a sure thing they were lucky to acquire for 10 times that amount. Goldfield, Cripple Creek, Cobalt, and Porcupine operators could relate many instances of finds made by trenching that have added millions to the world's store of bullion. Yet in spite of the evidence known to all well-informed engineers and practical mining men, only at intervals is it known how neglect of this simple elementary principle of mining has led to great waste of mineral or capital.

For instance, the other day it was learned that a certain 4-foot coal seam was mined by long wall and after scores of acres had been crushed and caved a 6-foot seam of superior coal was discovered only 40 feet vertically above. In this case a little shallow surface trenching through the loose alluvium covering the outcrop would have quickly shown the presence of the upper coal seam before mining started.

A more ridiculous case than this, however, was recently observed by the writer at Globe, Ariz. In the early days of a certain mine at this camp, the outcrop of a 6-foot vein of copper ore was discovered on a hill top. In order to gain depth on the vein, the prospectors started a would-be drift in a gully some hundreds of feet below, thinking to encounter the vein and drift in on the ore. Instead of trenching through the wash of the hillside slope, near the gully bottom to positively locate the outcrop, however, the drift mouth was located by guess and pointed toward the outcrop on the hill top. Suffice it to say that the drift was driven roughly 600 feet in hard rock before intersecting the vein at an acute angle. Had the prospectors first trenched the hillside, however, they would have located the vein outcrop not 50 feet from the mouth of their drift and so gone into the hill on fine solid ore that would have more than paid the expense of the development. As it was their finances were exhausted by the time ore was struck and they had the usual prospectors' experience of disposing of the property for a song. Such instances as these make the engineer weary, you say, and perhaps add—"If only those prospectors had sought the advice of some of us who know"—but listen.

In a certain recently discovered Nevada camp, the paying mines were all located at the foot of a hill. The depth of surface wash was here more than 50 feet deep, but 100 feet above the level of a certain shaft the rock outcrops were bare. Now certain Eastern investors believed that the mineral zone continued beyond the line of mines at the foot of the hill slope and out under the surface wash. They located the alluvium flat and proposed to locate their shaft not far from the line of established mines; they next hired a geologist to examine their property and report upon a feasible location for their shaft. His work was easy. The most superficial examination of the bare rock outcrops determined the fact that there were no fissures extending at right angles to the great group occupied by the developed mines, and out under the alluvium wash held by his clients. A short examination of the workings of the nearest mine confirmed his deductions from study of the outcrops. But the owners were not to be thus bluffed out of their valuable ground. So they picked a shaft location at a point commanding a splendid view of the desert valley and started sinking. They went 600 feet through wash, and then 200 feet through bed rock, cross-cut 500 feet to each side of the shaft, and then gave up in disgust.

SURFACE ALTERATIONS OF GOLD ORES

*By Albert D. Brokaw**

Experiments to Determine the Action of Surface Waters in Solution of Gold

The leaching of gold from the outcrop of auriferous lodes has been the subject of much discussion, and many contradictory statements regarding the chemistry involved have arisen in the literature. Frequently these statements are based on experimental evidence, and the contradictions may be explained in part, at least, by a lack of uniformity in the conditions under which the experiments were carried out, and a tendency to ignore the conditions of temperature and concentration of solution that we are justified in supposing to be operative in the surface alteration of such deposits.

At the suggestion of Prof. W. H. Emmons, the writer undertook a series of experiments with a view of determining which of the various solvents noted are most effective in the solution of gold. By limiting the problem to alteration, many substances are eliminated; only such as are known to occur in mine waters or in the gossan were studied, and the concentrations used are comparable to those shown by mine waters. The experiments were carried on at room temperature (18 degrees to 25 degrees), as Stokes† has shown that elevated temperatures have a very marked influence on the solubility of gold in ferric salt solutions.

A few of the solvents suggested by Don, Rickard, Lenher, and others, were made the subject of a comparative study, the conditions of temperature and concentration being practically uniform for the series. The substances studied were ferric sulphate, ferric chloride, sulphuric acid, hydrochloric acid, and manganese dioxide. These were covered by the following experiments, each in duplicate. Solution of gold is shown by loss of weight.

1. $Fe_2(SO_4)_3+H_2SO_4+Au$
   (*a*) No weighable loss.
   (*b*) No weighable loss.
2. $Fe_2(SO_4)_3+H_2SO_4+MnO_2+Au$
   (*a*) No weighable loss.
   (*b*) .00017 gram loss. (The duplicate was found to contain a trace of *Cl*, which probably accounts for the loss.)
3. $FeCl_3+HCl+Au$
   (*a*) No weighable loss.
   (*b*) No weighable loss.
4. $FeCl_3+HCl+MnO_2+Au$
   (*a*) .01640 gram loss. Area of plate, 383 square millimeters.
   (*b*) .01502 gram loss. Area of plate, 348 square millimeters.

The solutions were tenth normal‡ with respect to ferric salt and to acid. In each duplicate 50 cubic centimeters were used. In experiments 2 and 4, 1 gram of powdered manganese dioxide was added to each duplicate. The gold was obtained from Goldschmidt Bros., and assayed 99.9 per cent. pure. It was rolled to a thickness of about .002 inch, and cut into pieces of about 350 square millimeters area, and one piece, weighing about .15 gram, was used in each duplicate. The gold was washed with alcohol and ether and dried, then each piece was carefully weighed. The experiments were carried on in tightly stoppered test tubes, which were thoroughly shaken from time to time. After 2 weeks the pieces of gold were removed by means of a platinum wire, and washed with water, alcohol, and ether, in turn, before weighing. In experiments two and four, a small amount of manganese dioxide adhering to the plates was removed by means of a solution of ferrous sulphate acidified with sulphuric acid, after which the plates were treated as above. At the end of 2 weeks all but experiment 4 gave negative results when weighings were made to .0001 gram, and the balance was exchanged for one sensitive to .00001 gram, which was used from that time on. The whole time was 34 days. In experiment 4 it will be seen that the losses in (*a*) and (*b*) are approximately proportional to the areas of the plates.

The results of these experiments, as given above, show conclusively that, of the conditions under consideration, the most favorable for the solution of gold involve the presence of manganese dioxide and chloride. Although it is frequently stated that gold is readily soluble in ferric sulphate solutions, no loss of gold was detected after 34 days contact with a tenth normal solution of that salt.

In order to reproduce more nearly the conditions in nature, experiment 5 was prepared as follows: A solution was madeN/10 with respect to ferric sulphate and sulphuric acid, and N/25 with respect to sodium chloride. To 50 cubic centimeters of solution 1 gram of powdered manganese dioxide was added and the experiment was carried on as before. (This is essentially the experiment of Rickard, Trans. A. I. M. E., XXVI., 798. From experiments 6 and 7 it appears that the ferric salt is unnecessary.) The loss is comparable to that found in experiment 4, allowing for the shorter time and the greater dilution of the chloride.

5. $Fe_2(SO_4)_3+H_2SO_4+NaCl+MnO_2+Au$
   Loss of *Au* .00505 gram. Time 14 days.

The same experiment without MnO_2 showed no loss of gold.

After it had been shown that chlorides and manganese dioxide were necessary under these conditions, the next point to be determined was whether the free acid or the ferric chloride is the active agent in bringing about the solution. In experiment 6, 50 cubic centimeters of N/10 *HCl* was used with 1 gram of powdered MnO_2. In experiment 7, sodium hydroxide was added to 50 cubic centimeters of N/10 ferric chloride solution until the precipitate formed barely redissolved on shaking (even then the solution was somewhat acid owing to the hydrolysis of the ferric chloride), after which 1 gram of powdered MnO_2 was added.

6. $HCl+MnO_2+Au$
   Loss of *Au*, .01369 gram. Time, 14 days.
7. $FeCl_3+MnO_2+Au$
   Loss of *Au*, .00062 gram. Time, 14 days.

The experiments were conducted as before. The results show clearly that the free acid, rather than the ferric chloride, in the presence of managnese dioxide exercises the great solvent action, as the same amount of chlorine was present in both cases. Essentially, the most favorable conditions for the solution of gold are those in which free chlorine may be liberated.

W. J. McCaughey (in "Journal of the American Chemical Society"), in studying the solubility of gold in ferric salt solutions, found that ferrous sulphate, even in very small amounts, had a marked effect in depressing the solubility of gold. Conceivably this may be a factor to be considered, and with this in view experiment 8 was performed, to determine whether ferrous sulphate, in the presence of sulphuric acid and manganese dioxide, would be quickly oxidized to the ferric salt, according to the following equation:

8. $2FeSO+2H_2SO_4+MnO_2=Fe_2\ (SO_4)_3+MnSO_4+2H_2O$.

After acidifying 100 cubic centimeters of 1.6 *N*. $FeSO_4$ solution with sulphuric acid, it was shaken vigorously with 5 grams of powdered MnO_2. After 5 minutes the solution was filtered off. No ferrous iron was detected by the ferricyanide test, showing that the iron had been completely oxidized to the ferric state. The experiments were not done in such a way that the velocity of the oxidation could be measured, but the result shows that ferrous sulphate in acid solution is quickly oxidized by manganese dioxide, hence the suppression of the

† Stokes. Economical Geology, 1, 650.
‡ Normal as used in this paper refers to equivalent normal solutions. Tenth normal concentration was selected rather arbitrarily except for the fact that it is well within the range of concentration shown by mine waters. (See table of analyses.)

solution of gold by ferrous salts may be disregarded if manganese dioxide is present. It is interesting to note in this connection that the analysis of a sample of water from the Comstock lode (see analysis 3 in Table 1; Nos. 5 and 6 illustrate the same fact), showing the greatest amount of ferric iron, showed a considerable amount of manganese, but no ferrous iron; a condition in accord with the right-hand side of the above equation.

McCaughey's experiments on the solubility of gold in ferric salt solutions were made with stronger solutions than are known to occur in mine waters, but his results show that gold is attacked by ferric salts in the presence of hydrochloric acid.* While no loss of gold was noted in experiment 3, as carried out by the writer, it is possible that in a longer time some loss might be detected, as more dilute solutions act more slowly

* United States Geological Survey Bulletin 330, 547.
† Ibid.
‡ Bulletin University of California, IV, 192.
§ Ibid, 189.
‖ Beck, Nature of Ore Deposits (Weed), II, 377. Analyses expressed in milligrams per liter. Where necessary they have been recast.

From the above experiments, it appears:

1. That at the dilution of natural solutions of ferric salts their solvent effect on gold is probably very slight.

2 That in the presence of manganese dioxide no increased solubility is found unless chlorides are present.†

3. That mixtures of ferric sulphate, sulphuric acid, and sodium chloride in concentrations common in mine waters will readily dissolve gold in the presence of manganese dioxide.

4. That free hydrochloric acid in the presence of manganese dioxide has a much greater solvent effect than the same amount of chlorine in ferric chloride solution.

5. That the influence of ferrous salts in suppressing the solubility of gold is negligible if manganese dioxide is present.

* If gold is dissolved by ferric chloride the reaction might be expected to be as follows:

$$Au + 3\,FeCl_3 = AuCl_3 + 3\,FeCl_2$$

This would seem to be a reversible action, as ferrous salts are commonly used as a precipitant for gold. McCaughey, however (op. cit., foot-note, page 1,270), failed to detect any ferrous salt after the action had gone on for 2 days. It seemed probable that ferrous chloride had been formed, but was oxidized by contact with the air. Accordingly the experiment was repeated in an atmosphere of carbon dioxide, care being taken to exclude, as far as possible, all contact with the air. Several possible sources of error were not eliminated and the experiment is only of preliminary nature. The results were as follows:

	Loss of Gold	Weight of Ferrous Iron	
		Observed	Calculated
(a)	.02904	.0240	.02476
(b)	.03247	.0282	.02769

This seems to establish the correctness of the equation given above. The result is not in accord with the statement of McIlhiney (Am. Jour. Sci., Ser. IV. II., 293) who found that gold dissolved in ferric chloride only in presence of air. The greater dilution at which he worked may account for this.

† The influence of manganese compounds in chemical reactions involving oxidation is noted in many cases. E. g., Moissan (Chem. Minerale, V., 617) states that fuming hydrochloric acid in presence of air will dissolve gold, especially if manganous chloride is present. The catalytic action of manganese dioxide in the decomposition of potassium chlorate and hydrogen peroxide are well known. Probably manganese compounds are of considerable importance in natural oxidations, even though they may be present in very small amounts.

6. That the solution of gold is practically limited to the oxidized zone.

In the agreement with these experiments is the fact that manganiferous lodes bearing pyrite, in areas of chloride waters, are leached to greater depths than lodes that do not carry manganese.

Six complete analyses of vadose waters from their tables are given in Table I.

THE ALCHEMIST IN MODERN INDUSTRY*

In a plea for a more generous publication of results obtained in modern industrial research laboratories, Prof. Wm. H. Walker declared that the spirit of the old alchemy—namely, secrecy—was still in force, and depriving the world of much knowledge that the discoverers could share without harm to themselves.

There is a heavy moral obligation on the part of large industrial organizations having fully-equipped research laboratories, said Professor Walker, to contribute their share to the advance of the world's knowledge. They have well-stocked libraries, and are provided with all the current periodicals; they profit by all the scientific work which has been done and is being done. This is as it should be, and such firms are to be commended for their progressiveness. But is this not a reason why such laboratories should do their part in adding to the sum of available knowledge? There is in every laboratory much work which could be published and yet conserve the interests of the corporation. First, there are the results which may not have proved valuable to the laboratory in which they were obtained, but which would be of immense value to some one else working in an entirely different field. Second, there are those results of value to the laboratory possessing them, but which could be published in an unapplied or "pure" form and which would make an important contribution to science, and at the same time the publication would work no injury to the company or corporation most interested. And finally, there are those results of operations and processes, machines and apparatus which, if the truth were known, are possessed by a number of concerns, but are held as valuable secrets by each. Every one would profit and no one be the loser by so far-sighted and generous a policy. Germany is very justly held up before us as a shining example of marvelous industrial progress and prosperity. A very great deal of the credit for her present position is due to her splendid educational system. But no small factor in her national progress is the helpful attitude which her industrial organizations take toward the publicity of scientific data. The individual does not suffer, while Germany, both from a purely scientific and an industrial standpoint is rapidly advanced. But too often with us the president and his board of directors are alchemists; they fail to see why if they pay the salaries of their research men, they should give to the public, or their competitors, any part of their results. They exclaim: "What has posterity done for me?" They would have their laboratories remain the secret chambers of the alchemists, and continue to improve their methods of changing baser materials into gold without regard to the obligations which they owe to their fellows.

It requires no extensive mathematical calculation to prove that the manufacturers themselves would be the ones to profit by such a liberal treatment of the results of scientific work. Of 100 manufacturing concerns, each one would give but 1 per cent. to the whole contribution, while he would receive the remaining 99 per cent. He could not in the long run be the loser. But of vastly more importance, he would feel and know that his organization was taking part in a world movement toward that increase of human knowledge upon which all real progress depends.

*Abstract of paper by William H. Walker, Professor of Industrial Chemistry, Massachusetts Institute of Technology, Boston.

CHEMISTRY OF THE CYANIDE PROCESS

*By W. H. Seamon**

The progress that has been made in solving knotty problems in treating different ores with the cyanide process formed the basis of a recent article by Mr. W. H. Seamon, in the *Mexican Mining Journal.* "Much as we know," he says, "of the chemical reactions involved, we have scarcely begun to learn anything about the complex."

The Necessity of More Knowledge of the Effects of Various Compounds Resulting in the Process

Thirty-three metallic cyanides have been isolated by chemists; 250 cyanides are more or less known; something like 450 ferrocyanides and ferricyanides, including their double salts, have been slightly studied, and quite a large number of sulphocyanates and cyanates are more or less known. Any one of these compounds may occur in the treatment of ores by the cyanide process. While their chief physical and some of their chemical properties are known, yet practically nothing is known of their possible effects in the cyanide process; no systematic study has been attempted with reference to their influence in the winning of gold and silver. It is very desirable that a study be made of all these compounds, but it is a question likely to be overlooked. Scientists have other questions that interest them. Practical cyanide men have to get results and cannot afford to spend 2 or 3 years in preparation of a foundation for the chemical understanding of the cyanide process. Unless cyanide men get together and put up the funds to employ an investigating force, this knowledge will be accumulated very slowly.

This article is intended to be suggestive, rather than an epitome of the chemical facts known. No attempt is made to give credit to the many authorities from whom the facts have been gathered, it being considered sufficient to acknowledge indebtedness to everybody who has written on the subject.

Gold, particularly when finely divided, dissolves in aqueous solution of potassium cyanide in the presence of air, forming aurocyanide of gold and potassium according to the equation:

$$H_2O+2Au=2AuK(CN)_2+2KHO$$

The presence of oxygen is absolutely essential for this reaction. Some practical men have stated that they have made a good extraction without blowing air through the solutions. It is certain that in these instances the oxygen has been supplied in some way unknown or unconsidered by the gentlemen. It may have come from the oxides in the ores, but more probably from the small amounts of oxygen dissolved in most natural waters. The question has been thoroughly studied in the laboratory, under exact conditions, and even though gold has been extracted in practical work without the use of an air current the truth of the statement that it is necessary is not affected. The following are the conclusions of Christy, based upon actual work with ores:

1. The gold and silver are capable of dissolving at ordinary atmospheric temperatures and pressures to a limited extent, without the additions of oxygen or oxidizing agents.

2. At ordinary temperatures the atmospheric pressure has an indirect influence on the constancy of the dissolving action.

3. For the continued dissolution of gold and silver at ordinary atmospheric temperatures and pressures, oxygen, or an oxidizing agent, is desirable, if not absolutely essential.

4. Temperature has a direct influence on the dissolution of the metal, independent of the oxygen absorbed by the solution.

5. The value of oxygen absorbed by the solution is dependent on atmospheric pressure and to some extent on temperature.

The oxygen supply is best furnished by blowing air through the solutions. Strong oxidizing agents have been employed very successfully in some instances, generally at the expense of a larger consumption of cyanide, which is a compound easily decomposed. When there are reducing agents in the ores a larger supply of oxygen must be furnished.

Commercial cyanide is likely to contain small amounts of alkaline sulphides and their presence not only proportionately diminishes the solvent power of the cyanide, but may require a larger supply of oxygen.

Metallic silver dissolves in potassium cyanide solution precisely as does metallic gold. Oxygen is necessary for the chemical reaction and must be supplied by the introduction of air when not furnished otherwise. The double salt, potassium silver cyanide is soluble in four parts of water at a temperature of 20° C., and is dissociated by acids and sulphuretted hydrogen. The presence of alkaline sulphides in the cyanide is more detrimental in the solution of silver ores than in the case of gold ores. This statement will be contradicted by many practical men, but the experimental work in the laboratory, under known conditions, demonstrates the truth of this statement and the fact that in certain cases in practical work it has been observed that there was no detrimental action from the presence of alkaline sulphides must be explained on the theory that there was in the complex constituents of the ores treated something that neutralizes the deleterient effect of the alkaline sulphides, expected from the results of laboratory experiment.

In the cyaniding of silver ores containing silver sulphide minerals, the soluble sulphides should be removed, and oxygen is an important agent in the decomposition of the sulphides even in the presence of lead salts. A chloridizing roast is always beneficial for most silver minerals, although it is not essential, and is seldom employed in the cyanide treatment of silver ores. A chloridizing roast will largely increase the extraction and obviate the presence of oxygen at the time of action of the cyanide solution.

In handling silver ores the reactions are more complex than in handling ores of gold, owing to the greater chemical activity of silver as well as to the fact that the solutions of cyanide used are necessarily much stronger. It is in the handling of silver ores that it is so important that more knowledge should be secured concerning the parts played by the various double cyanides, ferrocyanides and ferricyanides, in the solution of silver.

No simple cyanide of iron has, as yet, been isolated; they are, if they exist at all, very unstable and occur only in solution, decomposing when attempt is made to secure them in a solid state. It is well known that iron and steel and various iron oxides consume varying quantities of cyanide. The compounds of iron which most readily form ferrous salts consume the largest quantities of cyanide. While cyanides of iron are practically unknown, the ferrocyanides have been isolated and studied, and they are always formed in the cyanide process. As metallic iron and pieces of steel break off from the wearing parts of the machinery employed in preparing ores for cyanide treatment, it is important that a careful study should be made of all the possible influences of the ferrocyanides in the solution of gold and silver.

The sulphides of iron, as marcasite and pyrite, are also commonly occurring constituents of ores and they are large consumers of cyanide. All of the sulphides of iron decompose more or less rapidly in the presence of water and form soluble ferrous and ferric salts. When air is used in agitation there is a marked increase in the decomposition of the sulphides of iron. Some authorities advise preliminary washing out of all ferrous salts before adding cyanide solutions.

The salt $Zn(CN)_2$ is known and several double cyanides, corresponding in formula to the potassium zinc cyanide, $Zn(CN)_2 \cdot 2KCN$. These double cyanides are known to be solvents for gold, but, as yet, their influence in the extraction of gold has not been completely determined. They are sure to occur in varying amounts in the treatment and it is very important that more should be known of their properties and

* Abstract of article in *Mexican Mining Journal.*

effects. It has not been determined what effect the formation of the double cyanide of zinc has in preventing the precipitation of gold in the zinc boxes. It is well known that the salt helps dissolve gold when the solutions are reused.

Chemists know many double manganese cyanides and many more ferrocyanides, but their relations to the cyanide process are not known. The same may be said of aluminum, barium and calcium cyanides and ferrocyanides. It is known that calcium carbonate, a constituent of ores, is acted upon by alkaline cyanides, resulting in a consumption of cyanide. So long as the solutions are kept alkaline the loss is negligible.

All commercial cyanide contains more or less sodium cyanide, and so-called 125 per cent. cyanide is nearly pure cyanide of sodium. There is no scientific reason known why the sodium salt should not be as good a solvent of gold and silver as the potassium cyanide; it is a fact that pound for pound it possesses greater solvent power and can be produced more cheaply. These things make it especially desirable, and it is a matter of surprise that many cyanide men have found the sodium salt less efficient than the potassium. The problem has not been thoroughly worked out, but I am satisfied that when the facts are accumulated, it will be found in favor of the sodium cyanide.

Recently, there has been an awakening to the fact that many brands of cyanide are not so cheap as their price would indicate. For a long time but little attention has been paid by consumers to the impurities existing in different brands of cyanide. It will not be long before the sellers will have to sell on guaranteed analysis.

STANDARDIZATION OF BULLION ASSAYS*

Report of Committee "B," Institution of Mining and Metallurgy on Bullion and Assay Values

The committee for the standardization of bullion and assay values was formed for the purpose of recommending rules which shall, as far as possible, be followed by assayers, metallurgists, and mining men, in reporting the results of assays and of metallurgical, dressing, and other tests or which assays form an essential part, so that ambiguity shall be avoided and the possibility of misinterpretation or misuse of reports shall be minimized.

Reports of assay results, extraction tests, metallurgical, and ore-dressing trials, etc., are sometimes so worded as to permit a wrong interpretation, and the committee urges the necessity for definite statements as to the nature and condition of the sample as assayed, and, where advisable, an indication of the method of assay. Thus, in the case of such metals as copper, tin, lead, antimony, etc., where both "wet" and "dry" methods of assay are in use, results should be reported as obtained by "fire" assay or by "wet" assay, with further details as to method, if judged advisable. Similarly, it should be stated whether the sample was assayed in the condition in which it was received or "air dried" or dried at —°C.

In reporting that an assay for such a constituent as tin, arsenic, tungstic acid, etc., corresponds to so much "black tin," "white arsenic," "wolfram" or other recognized saleable product, the report should give the assay result for such constituent, together with a definite statement as to the figures used in calculating such saleable product. Thus, an assay showing 1 per cent. of metallic tin might be reported as 1 per cent. of metallic tin, equivalent, if all could be extracted as such, to 1.5 per cent. of "black tin" containing 66.6 per cent. (or two-thirds) of its weight of metallic tin. Similarly, in reporting results, where assay values might be mistaken as representing available produce, it should be stated that such are merely "gross" assay values, a statement or estimate of the actual "commercial" values being added whenever possible.

In such matters as ore dressing, ore-treating processes, furnace work, etc., where so much depends on the way in which results are reported, on the nature of the sample and on the method of taking it and its relation to other samples, the committee emphasizes the necessity for careful phraseology and for the inclusion of exact data, as also the necessity for care in preparing, describing, labeling, sealing and otherwise ensuring the correctness and authenticity of samples submitted for tests or assays.

The Bullion and Assay Values Committee submit the following recommendations for adoption by the Institution:

1. Assay reports shall state the exact condition of the sample as to dryness when assayed.

2. Assay values of gold and silver ores and products shall be represented in pennyweights and decimals or in ounces and decimals, and not in oz., dwts., and grains. They shall be expressed in terms of fine gold and fine silver, respectively, not as "bullion."

3. Assay values of alluvials shall be reported in grains and decimals of a grain of "fine" gold, or in pence (at 2d. per grain of "fine" gold), or cents per cubic yard.

It is recommended that, in the absence of specific information, one cubic yard of ordinary alluvial, excluding boulders, be taken as equivalent to 3,000 pounds (1½ short tons).

4. In reporting assay values of cyanide and other solutions, the results shall be given in parts by weight in a stated volume of the solution. (In the case of cyanide solutions, the use of the "fluid ton of 32 cubic feet" is recommended. It closely approximates to 2,000 pounds and is in common use.)

5. When it is necessary to state or estimate the money value of an ore, etc., (other than of gold), it shall be accompanied by the assay value, and the basis on which the former has been calculated from the latter shall be stated.

6. Laboratory sieving tests shall be made with the I. M. M. standard sieves, or, when other sieves are used, the widths of the apertures shall be stated.

With the above recommendations, if approved, will be included the following, which have already been adopted on the recommendation of the Weights and Measures Sectional Committee:

(*a*) The word "ton" shall represent a weight of 2,000 pounds avoirdupois (29,166.6 ounces troy).

Note.—It is advisable to abandon the use of the terms hundredweights and quarters, and to express fractions of a ton in pounds, or in decimals of a ton.

(*b*) The word "gallon" shall represent the imperial gallon measure of 10 pounds of water.

(*c*) Temperatures shall be expressed in degrees centigrade.

(*d*) Returns of gold and silver shall be expressed in terms of fine gold and fine silver, respectively, not as "bullion."

(*e*) Gold contents of ores, etc., determined by assay, shall be expressed in money values as well as in weights; and in this connection the value shall be taken (as a convenient constant) at 85 shillings or $20.67 United States currency, per troy ounce of fine gold.

*Before finally adopting the recommendations of the Committee, the Council will be glad to consider any suggested alterations or additions, which should be received by the Secretary The Institution of Mining and Metallurgy, not later than June 30, 1910.

COPPER REFINING

The largest copper refining plant in the world is located in Brooklyn, and is known as the Laurel Hill works of the Nichols Copper Co. At this plant there are copper smelting furnaces, converters for bessemerizing copper matte, and the necessary furnace paraphernalia in connection with casting copper anodes, wire bars, slabs, etc. There is also an extensive sulphuric acid plant that utilizes the excess sulphur from the copper ores.

THE CROWN MINES, LIMITED*

The property embraces, from the east, the Robinson Central Deep, Crown Deep, Crown Reef, and South Rand; Langlaagte Deep, Langlaagte Royal, and Pearl Central on the west, and in addition 1,278 claims of deep-level ground. In extent it is about 3 miles from east to west on the strike of the reef.

Electric Hoisting and Haulage. A Successful New Cyanide Plant of Large Capacity

There are on the property nine main shafts and seven crusher stations when including those at the Pearl Central and Langlaagte Royal, and the property is being so laid out, both on the surface and underground, that in the future there will be only two large crusher stations; one at No. 5 and one at No. 7 shafts. By a system of underground chutes and haulage, the rock from the Langlaagte Royal, Pearl Central, Langlaagte Deep and western areas will be concentrated at No. 7 shaft and hoisted there, while all the rock from the eastern section will gradually be concentrated at No. 5 shaft. These two shafts will have to handle between 9,000 and 10,000 tons daily, or the full requirements from the mine. The two shafts will be connected on the thirteenth level at a vertical depth of approximately 2,200 feet. This level will be a main haulage level, the main drive being 14½ feet wide and practically straight from one end of the property to the other. This drive will be served by electric haulage, so arranged that ore may be delivered to either shaft.

The No. 7 shaft is vertical to inclined, with three hoisting compartments and a pump way. Alterations are in progress to convert the hoisting at this shaft into double stage with four hoisting compartments in the vertical, for 4-ton skips, and four hoisting compartments in the incline for 5-ton skips, all hoisting to be done by electricity.

The No. 7 shaft crusher station is the western station of the Crown mines, and is being equipped to handle 3,500 to 4,000 tons of ore on one day shift only. The special features at this station are three 30-inch conveyer belts delivering into nine 30″×12″ Hadfield & Jack crushers. The return sides of these belts are utilized for waste, which is delivered to a transverse belt delivering to the waste bin and thence to dump. The rock from the crushers is caught in bins of 1,000-tons capacity, thence it is discharged through pneumatically operated ore gates into 40-ton hopper cars. These cars are hauled in trains by 50-ton electric locomotives, and may be delivered to any one of the mills of the Crown mines. The cars are constructed so that their discharge may be pneumatically controlled from the locomotive, thus reducing the labor required to a minimum.

The No. 5 shaft has a vertical depth of 3,400 feet. Three main haulage levels will be established in this shaft at distances of 600 feet apart, vertical. These main haulage levels will be the thirteenth, sixteenth, and nineteenth, and they will control all the ore down to the South Rand dike. On each of the levels electric haulage will be installed. At each of these levels the ore bins will have a capacity of 2,000 tons, and winding will be done by three 8-ton electric hoists, as large, if not larger, than any electric hoists in the world.

The No. 5 crusher station will be similar to that at the No. 7 shaft, except that its capacity will be from 5,000 to 6,000 tons per day of 10 hours.

The present metallurgical equipment consists of 675 stamps, 20 tube mills, and sand and slime plants made up as follows: Crown Deep, 300 stamps and 10 tube mills; Langlaagte Deep, 200 stamps and six tube mills; Crown Reef, 120 stamps and three tube mills; Bonanza, 55 stamps and one tube mill.

With the present plant there is a capacity of 165,000 tons per month.

A fifth mill is being erected of more modern type, which, when completed, will increase the total crushing capacity to more than 200,000 tons per month. The special features are the tandem classifications and the tube milling at Crown Deep plant.

The installation of a 300-leaf Butters vacuum-filter slime plant at Crown Reef plant is interesting not only on account of its being the first vacuum-filter plant erected on these gold fields, but that it should occupy the site of the first slime plant designed and erected on the Rand by Mr. J. R. Williams in 1894.

The Butters vacuum-filter plant consists of two stock vats equipped (temporarily) with air agitation to keep the slime in suspension. After the gold has been dissolved in Brown agitators, the pulp at a dilution of 2 to 1 is transferred to the stock-pulp vats from which it is fed to the filters as required. There is one wash-solution vat. All precipitated solution is delivered to this vat to be used subsequently for a wash solution in the filters. There are two filter boxes each fitted with 150 Butters patent vacuum filter leaves and one 14″×14″ Gould vacuum pump. Each filter box is an independent filtering unit. One 10-inch Robeson–Davidson slime pump handles the pulp and solution to and from the filter boxes and the stock vats, serving the boxes alternately. The piping is arranged around the pump in a loop, having four valves interposed so as to reverse the direction of flow through the pipes. The pump is set in either the emptying or filling position instantly by means of one pilot valve introducing hydraulic pressure into the cylinders of the four valves simultaneously. The motor for the 10-inch slime pump and the valves in the pump systems are operated from the switchboard. The kind of filtering and treating cyanide slime is called the "pumping system," and the process of filtration is performed as follows:

To form the cake, the filter box is filled with pulp to a point over the top of the filter leaves, and a valve opened connecting the vacuum pump directly with the filters. Clear cyanide solution is drawn from within the filter leaves and delivered to the clarifying vat for precipitation, the slime remaining as a cake on the outside of the filters. The filters are kept submerged by refilling the box at intervals, and jets of air are introduced at the points of each hopper to keep the slime in suspension. When a cake 1 inch to 1½ inches thick has been formed, the surplus pulp is pumped back to the stock-pulp vat, and the box is then filled with solution to wash the cake. During the time of forming and washing the cake, the vacuum is maintained at the highest possible point, but when the cake is exposed to air during the transfer of pulp and wash solution, the vacuum is reduced to 5 inches to prevent the cake cracking.

The cake being formed by atmospheric pressure, the resistance and permeability is equal over the whole surface of the leaf, thus producing an ideal condition for the recovery of the valuable moisture contained therein, which equals 30 per cent. to 35 per cent. Sufficient wash solution (about 2 tons per ton of slime) is drawn through the cake by the vacuum pump to effect a complete displacement of the original moisture. A portion of this solution goes to the clarifying vats for precipitation; the flow is then diverted to a stock vat to be used in making up new charges in the Brown or Pachuca treatment vats.

When the wash is complete, the vacuum is disconnected and a reverse flow of solution (by gravity from the vat on the roof) is introduced to the interior of the filters, causing the cakes to drop. The surplus solution is then pumped from the filter box through decanters and returned to the wash solution vat. The mass of thick sludge remaining in the box is diluted with water and agitated with air for a few minutes to make a homogeneous pulp of 1 to 1, which is then pumped to the residue dam by a second 10-inch pump, the delivery pipe of which is fitted with an automatic sampler. One complete cycle of operations occupies the following times: Filling box with pulp and forming cake, 45 minutes; transferring and washing and forming cake, 70 minutes; discharging and washing and forming

*From Journal of the Chemical, Metallurgical and Mining Society of South Africa.

cake, 20 minutes; total time of cycle, 2 hours and 15 minutes; tons treated per cycle, 1¼-inch cake, 50 tons each box.

Five leaves are removed from each filter box every day, thoroughly washed with a spray of water and air, and then immersed in a vat of 2-per-cent. hydrochloric acid solution, for the purpose of dissolving the calcium carbonate and keeping the leaves soft, pliable, and in good working condition. The *HCl* solution is passed through the leaves in reverse directions alternately by means of an automatic arrangement that requires no power or attention. The leaves are removed from the acid bath after 4 to 6 hours' treatment, again washed with the spray of water and returned to the filter box.

In January a special test was made on current slime, treated first by the Adair–Usher process, the residues from which were delivered to the filter for the purpose of determining what further recovery of dissolved gold was possible by filtration. In this test, as also in the former operations with accumulated slime, the efficiency of the filter was fully demonstrated, assays of the residues showing consistently during the whole period over 99 per cent. recovery of dissolved gold.

There is some dissolving of gold, incidentally effected, during the process of filtration; however, the Butters filter is essentially a slime-washing machine, purely mechanical in its functions, and might be termed a process of forced decantation.

The plant was designed to treat 500 tons per day. Subsequent operations proved that, owing to the exceptional adaptability of Rand slime to filtration, it has a capacity of 900 tons per day.

The plant was put in commission on August 12, 1910, and after a most exacting test over a period of 6 months, has been formally taken over by the Crown Mines, Ltd., as a part of their permanent plant.

THE A B C OF ELECTRICITY IN MINES*

In an electric motor, the thing that does the work is the current; and the entire power plant and system is calculated to generate and force through the motors a sufficient amount of current to make them do their work.

Definitions. Drop in Voltage. Calculation of Resistance of Conductors

The current of electricity is in many respects like a current of water. As water flows through a pipe, so the electric current flows through a copper wire. As the walls of the pipe retard the flow of water by friction, so a copper wire retards the flow of the electric current by friction or resistance. The great difference is that water flows through the hole in the pipe, while the electric current flows through the body of the metal itself. In order to guide the electric current to its destination, the copper wire or "conductor" is surrounded by a "non-conductor," or an "insulating" material; that is, a material through which the electric current will not flow. Air is a non-conductor, so that a bare wire in air will carry a current through its length. Water is a conductor, so a bare wire in water will allow the current to flow in any direction.

As the resistance to the flow of water varies with the length and size of the pipe, so the resistance to the flow of the electric current varies with the length and size of the "conductor" wire.

The pressure, called the "voltage," which forces the electric current to flow through a wire, corresponds closely to the pressure from the pumps of a water system. If the water pipes are full of water, but the water is not flowing, the pressure at the end of the line will be the same as at the pump. But as soon as the water begins to flow, the pressure at the end of the line drops, the amount of the drop depending on the amount of water flowing. So, if there is no current flowing in a trolley wire, the voltage at its far end will be the same as at the generator. If current is being used at the far end of the trolley line, the voltage will drop at the end of the line, the "drop" depending on the amount of current flowing.

A difference between a current of water in a pipe and a current of electricity is that the water flowing out of the end of the pipe is used and thrown away; while the electric current flows through the motor and then returns to the generator. That is, the same current flows round and round the circuit. So in order to get the total resistance of the circuit, the resistance of the rail return must be added to the resistance of the trolley circuit from the generator to the motor.

In order to be able to figure definitely how much copper is needed in a circuit, the resistance of the copper is measured in units called "ohms." 00 wire has a resistance of .0778 ohm per 1,000 feet, 000 wire of .0617 ohm per 1,000 feet, and 0000 wire of .0489 ohm per 1,000 feet.

The drop in voltage in the line is equal to the number of amperes flowing multiplied by the number of ohms resistance in the circuit. For instance, if a motor using 200 amperes current is running at a distance of 4,000 feet from the generator, and if the track return circuit has one-half the resistance of the trolley wire, which we will say is 0000, then the total resistance would be

$$4\times.0489+\frac{4\times.0489}{2}=.2934 \text{ ohm,}$$

and the voltage drop would be

$$200\times.2934=58.68 \text{ volts.}$$

If the generator holds 260 volts, this would leave 201.32 volts to run the motor. If a cutting machine using 100 amperes is running at the same time, the drop in voltage would be

$$300\times.2934=88.02 \text{ volts,}$$

and would leave but 171.98 volts for the motors. If the motors will not operate well on less than 200 volts, it would be necessary to add some feeder wire. Suppose a 0000 feeder wire be added. That would reduce the trolley resistance by one-half, and the total resistance would be

$$\frac{4\times.0489}{2}+\frac{4\times.0489}{2}=.1956 \text{ ohm,}$$

and the voltage drop would be $300\times.1956=58.68$ volts, and would leave 201.32 volts to run the motors. If the load be increased, still, it will become necessary to add more feeder wire.

To obtain the resistance of two conductors "in parallel," that is, placed side by side and connected at intervals so that they assist each other to carry the current in the same direction, divide the product of their separate resistances by their sum. Thus, the resistance of a 0000 wire ($R=.0489$ ohm per 1,000 feet) "in parallel" with a 500,000 C. M. feeder ($R=.021$ ohm per 1,000 feet) is

$$\frac{.0489\times.021}{.0489+.021}=.0147 \text{ ohm}$$

per 1,000 feet. The resistance for 4,000 feet would be

$$4\times.0147=.0588 \text{ ohm.}$$

Assuming the track resistance to be the same as above assumed, .0978 ohm, the total resistance would be

$$.0978+.0588=.1566 \text{ ohm,}$$

and the voltage lost in the wire and rail with 300 amperes flowing would be

$$300\times.1566=46.98 \text{ volts.}$$

In adding feeder copper to a circuit, it is very important that it be added at the right point. For instance, suppose the trolley resistance is 1 ohm and the track resistance is 2 ohms. If the trolley is 0000 wire and a 0000 feeder wire be added to it, the trolley resistance would be ½ ohm and the total resistance 2½ ohms If, however, the 0000 feeder had been added to the track, its resistance would then be

$$\frac{1\times2}{1+2}=\tfrac{2}{3} \text{ ohm,}$$

or the product of track resistance and copper resistance in parallel, divided by their sum, and the total resistance 1⅔ ohms. This change in location of the feeder thus reduces the resistance by ⅚ ohm, or 33⅓ per cent.

* By W. Kempton, Eng. Dept. Ohio Brass Co.

In short, the trolley and feeder resistance should be kept as nearly equal to the track resistance as possible. In the case cited in the second paragraph above, the next addition of copper should be made to the track, for its resistance is now more than the trolley.

To summarize, if a mine operator finds in operating his motors any difficulty on account of lack of power he should take a voltmeter into the mine and read the voltage between the trolley wire and rail while all motors are running at full load. Better still, take a voltmeter on the motor and read the voltage during its run, noting voltage particularly at points of poorest operation. If the generator maintains the voltage about constant and the drop is excessive, say 30 per cent., the trolley and track resistance is responsible.

To determine if the track resistance is excessive, two methods may be followed. One is to get the full load current rating of the various machines used in the mine from the makers. From this and the number of various machines and motors running at once from the trolley circuit, determine the largest amount of current carried by the circuit at one time. From the size and length of the trolley wire and feeders the resistance can be figured. Then by multiplying the number of amperes above by the trolley circuit resistance, the voltage lost in that part of the circuit will be obtained. This value subtracted from the total maximum drop will leave the voltage lost in the rail circuit. The rail loss divided by the current will give the rail resistance. If the rail resistance is more than .024 ohm per 1,000 feet, the bonds should be gone over and the poor ones replaced.

A more accurate method of getting the resistance would be to take an ammeter of sufficient capacity and connect it into the trolley line, say at a section insulator point with switch on the wall, and read the current and voltage at the same instant. The readings must be taken on the main entry at a point where all current used at that instant is flowing through the ammeter. The point selected should be as far from the mouth of the mine as possible, and the trolley and track length should be measured from this point to the generator.

The first method, though less accurate, will probably be the more practical for the reason that an ammeter of the proper capacity will be harder to secure than the voltmeter, as every mine having electric haulage should be provided with a portable voltmeter.

If it is found that the rail resistance is high, a bond-testing set should be secured and every bond tested. Those having too high a resistance should be replaced by good ones. The importance of good bonding is often overlooked; but when it is found that the difference between poor and good bonding often represents the difference between the addition or omission of an extra feeder, its importance will be appreciated.

PHOSPHORUS POISONING

The results of an investigation of phosphorus poisoning in American match factories are presented in Bulletin No. 86 of the Bureau of Labor of the Department of Commerce and Labor. This investigation was recently made by Dr. John B. Andrews, secretary of the American Association for Labor Legislation, in cooperation with the Bureau of Labor.

The manufacture of matches where white phosphorus is used, as in all American factories, exposes all employes who come in contact with the phosphorus or its fumes to the dangers of phosphorus necrosis. The phosphorus most frequently attacks the jawbones and not infrequently necessitates the removal of an entire jaw by surgical operation. It is the experience of all factories and all countries, that so long as white phosphorus is used the danger cannot be entirely eliminated, although it may be much diminished by thorough ventilation, and by the rigid enforcement of preventive measures.

Detailed investigation of 15 match factories showed that 65 per cent. of the employes were working under conditions exposing them to the fumes of phosphorus and the dangers of phosphorus poisoning. The employment of women and children is such that they are much more exposed to the dangers than are the men. Ninety-five per cent. of all the women and 83 per cent. of the children under 16 years of age were exposed to the dangers of the poison. The total number of employes in the 15 factories investigated was, according to the statements made by the manufacturers, 3,591, of whom 2,024 were men, 1,253 were women 16 years of age and over, while children under 16 numbered 314, of whom 121 were boys and 193 were girls.

A movement, which had been growing for a number of years, for the prohibition of the use of white phosphorus culminated in 1906 in the international convention of Berne, called on the initiative of the International Association for Labor Legislation. As a result of this convention the leading countries of Europe joined in a treaty to prohibit the manufacture, importation, and sale of matches made of white phosphorus.

Great Britain for a while held aloof from the movement, endeavoring to control the danger by the strictest kind of legal regulation. After a trial of a number of years the effort was admitted to be a failure, and legislation was, therefore, enacted which became effective the first of the present year, by which Great Britain joined the alliance of the countries prohibiting the manufacture, importation, or sale of white phosphorus matches.

A harmless substitute for white phosphorus, that is commercially practicable, has been found in the sesquisulphide of phosphorus, and is largely in use abroad in the manufacture of the "strike anywhere" match. For the safety match, red phosphorus, which is not poisonous, is generally used.

The United States is practically the only commercial country of any importance which has not taken any step to prevent the unrestricted use of this poisonous substance in the manufacture of matches.

While several states have enacted laws prohibiting the employment of children under 16 years of age in certain operations in match factories, no state has yet made any adequate provision for the protection of the health of workers over 16 years of age in the match industry, although for over 50 years the dangers of working with white phosphorus have been known and recognized in this country.

The owners of the harmless substitute for white phosphorus in this country have since the above was sent out by the Bureau of Labor offered the use of their patent free of royalty and without stipulation to all match factories in the United States.

TREATMENT OF COBALT ORES

There is still much to be discovered in the treatment of Cobalt silver ores. During 1910 the Canadian Copper Co. treated 4,900 tons of silver ore averaging 1,730 ounces to the ton. The product of this smelter is speiss and base bullion, the latter being retreated until it is ready to be shipped as refined silver. The speiss is milled and desilverized by a wet process. Crude cobalt material is obtained as a residue which is in the usual form purchased by cobalt manufacturers. As a result of improvements on this plant the Canadian Copper Co. is shipping refined silver, refined arsenic, and a marketable cobalt product. The changes have increased the capacity of the plant to over 800 tons per month, so that it has a monthly output of silver of over 1,000,000 ounces. Another result of the enlargement of this plant and the modifications in the process followed is the quicker return made shippers, the smelter people being able to pay for 70 per cent. of the silver in 30 days and for the remaining 30 per cent. in 60 days.

The Coniagas Reduction Co. consider that white arsenic and cobalt are as profitable as formerly. In other words, they state that at 2½ to 3 cents arsenic is unprofitable, but as they are obliged to handle it, it is a profitable by-product. The Reduction Works are paying 8 cents a pound for cobalt when ores assay 6 per cent. or more, 10 cents for 8-per-cent. ores, and 12 cents for 12-per-cent. or more.

PROSPECTING POVERTY GULCH CLAIMS

By Charles W. Henderson

(Continued from May number)

Surface Indications. Prospecting With Trenches and Underground. Materials Used. Cost and Progress

Surface Indications.—The veins in Cripple Creek, Colo., more particularly those of phonolite, have a similarity with the dikes in their strike and dip, thus suggesting some sort of relationship between them. Owing to soil and talus covering the deposits, surface outcrops are of rare occurrence, making it necessary to trench, and it is proposed to uncover two typical Cripple Creek dikes dipping in opposite directions, with the vein following their intersection at an angle of 23 degrees dip, though typical Cripple Creek veins are nearly vertical. The basic dike is exposed in Poverty Gulch where the railroad crosses, and also at the head of the creek which empties at the southwest corner of the Golden Cycle claim. The distance between these outcrops is 1,500 feet, and between these two points the dike is covered with soil from 10 feet to 15 feet deep. The dike at the outcrop is from 5 feet to 10 feet wide and seems to continue in a northerly

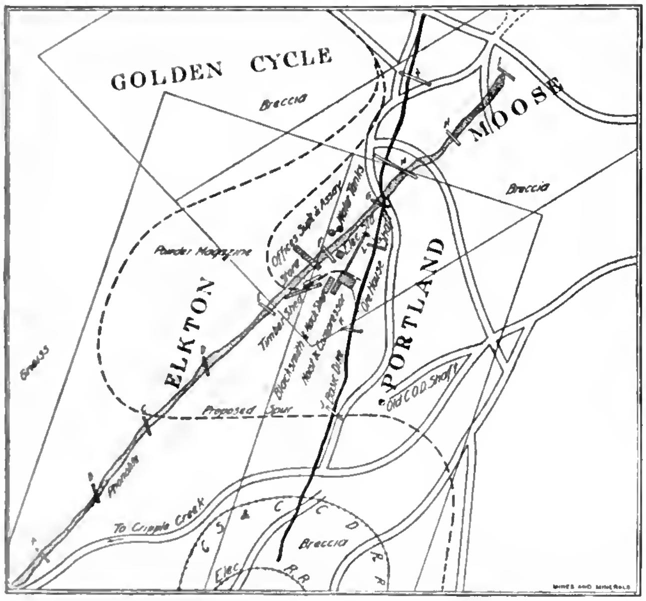

Fig. 1. Map Showing Location of Mine

direction. It is decomposed and not easily distinguished from andesite breccia, which is the country rock of Cripple Creek, for the most part at least.

On the road to Cripple Creek there is a hard compact phonolite dike striking N 40° E and dipping 60° in a N 50° W direction. This dike is readily identified, for which reason the first prospecting work is to prove its existence, by trenching and tunneling; work is therefore started at *A*, Fig. 1, and it is proposed to make trenches at intervals of 100 feet along the outcrop. During the course of the work itemized costs are to be kept for future reference and to show profit and loss of the undertaking.

Trench *A* 60 feet long is excavated 6 feet wide by 7 feet deep without any indication of bed rock. This work was done by 6 men with picks and shovels in 3.2 days and the following data were obtained:

$\frac{60' \times 7' \times 6'}{27} = 93.4$ cubic yards, material handled; or $\frac{93.4}{3.2 \times 6 \times 8}$ $= .6$ cubic yard per man per hour or 4.8 cubic yards per man in 8 hours. As men cannot throw dirt with a shovel to advantage more than from 4 to 6 feet from the trench, a staging was put in, the trench narrowed to 3 feet, and 3 additional men hired to rehandle the dirt. The capacity of the 9 men shoveling with two throws was equal to 6 men shoveling with one throw, but the cost was increased 50 per cent. for labor. The second stage was excavated in $\frac{60' \times 8' \times 3'}{27 \times 4.8 \times 6} = 1.85$ days.

The cost of excavating 146.7 cubic yards of earth from the trench was as follows:

Six men 3 days @ $3	$54.00
Nine men 2 days @ $3	54.00
Six round-point long-handled shovels	9.75
Three square-point D-handled shovels	4.00
Six 5-pound drift picks	8.00
Six 36-inch drift pick handles	1.90
172 feet lumber for staging	3.10
	$134.75

Cost per cubic yard, $.918.

The results obtained from this trench decided the feasibility of prospecting by a series of cross-cut drifts spaced 250 feet apart. The approaches were dug in the soil on the side hill until a face 10 feet square was obtained. The sides of this cut were given a 1 to 1 slope to prevent their falling in, and a drift set was erected at the face to prevent the portal caving. Three drifts were started with 9 men, three at each drift, who completed the approaches in 2 days, from which it was ascertained that 2 men with pick and shovel and 1 man wheeling could do about as much work as 2 men in a trench. When tunneling in soft earth a man can pick, shovel, wheel and waste, when the run is not long, say 25 feet, about $\frac{3}{4}$ as much as he can shovel and pitch from a trench, or $\frac{4.8 \times 3}{4} = 3.6$ cubic yards. When a rock face was reached, 2 men at each drift were put at work with single hammer and drills, while the third man of the party was occupied in mucking, carrying steel from the forge, etc. A blacksmith was hired at $4.50 a day, who also superintended the work and did the panning and sampling as the work progressed. Each tunnel was driven through the dike and through the ore in drifts *B* and *C*, and side drifts were driven 10 feet in the direction of the strike up the slope. There was 85 feet of drifting done in the prospect drifts *B*, *C*, and *D*.

In drifting, 11 holes were drilled in each face $2\frac{1}{2}$ feet deep, making an advance of 2 feet for each round. Each man was able to drill 1 foot an hour, and with six drilling, two in each tunnel, each 2-foot advance took 11 holes, $2\frac{1}{2}$ feet deep, or $27\frac{1}{2}$ feet. Two men in each tunnel drilled 16 feet a day, making a new round every day and a half by working from 7 a. m. to 1 p. m. in the morning shift, so that shots could be fired at the noon hour. Each shot broke down 2.6 cubic yards, which was readily mucked and wheeled by the laborers.

The following data were obtained from this work: $\frac{85'}{2'} = 43$ rounds of shots that demanded 27.5 feet of drill hole for each round. Since 6 men drilled 48 feet per day the advance required $\frac{27.5 \times 43}{48} =$ approximately 25 days. In all, there were 473 holes drilled, and each was charged with $2\frac{1}{2}$ sticks of $\frac{7}{8}'' \times 8''$ dynamite weighing .25 pound each or .625 pound per charge. The total quantity of explosives used was $\frac{473 \times .625}{50} = 6$ fifty-pound boxes.

The diameter at the mouth of a 6-foot hole need not be more than $\frac{3}{8}$ inch greater than at bottom, with $\frac{1}{8}$-inch reduction in 2 feet possible in very hard rock. The least admissible diameter of hole at bottom for dynamite is $\frac{3}{4}$ inch. The steel used was $\frac{7}{8}$ inch octagonal with $1\frac{1}{4}$-inch starting bits decreasing to 1-inch bits to finish. The drills were dulled every 2 feet of drilling with usually two starters required for the 2 feet.

The following lengths comprised a set of steel: 3 feet, $2\frac{1}{2}$ feet, 2 feet, $1\frac{1}{2}$ feet, and 10 inches; and each man in drilling 8 feet a day put in a little over 3 holes, using a set of steel in the operation. This made, for the six men working, six sets of

5 or 6 pieces each, or from 30 to 36 pieces of steel to be sharpened a day.

COST OF DRIVING THE CROSS-CUTS

One foreman 25 days @ $4.50	$112.50
Nine laborers 3 days @ $3	81.00
Three laborers 25 days @$3	225.00
Six miners 25 days @ $3.50	525.00
Three wheelbarrows @ $13.50	40.50
Six $4\frac{1}{2}$-pound striking bammers	10.80
Six 12-inch hammer bandles	.60
344 pounds, 132 feet $\frac{7}{8}$-inch steel	20.58
300 pounds dynamite @ $.101 per pound	30.46
1.5 tons charcoal @ $20.75	31.12
171 feet lumber for portals	3.42
One portable forge	42.00
One 90-pound anvil, steel faced	9.00
One set blacksmith tools	9.00
600 candles @ $.0145 each	8.70
172 assays, four for each round	57.00
473 fulminate caps, 85 cents per 100	4.02
1,419 feet double tape fuse @ 65 cents per 100 feet	9.22
	$1,219.72

When opening cross-cuts *B* and *C*, 10 feet were driven on ore that assayed 1.209 ounces of gold per ton and which amounted to 42 tons. This was hauled to the railroad, shipped to a smelter which purchased it at $18.13 per gross ton. The smelter return was as follows:

Gross Pounds	Moisture Per Cent.	Net Pounds	Ounces Gold Per Ton	Value Per Ton	Total Value
84,000	2	83,832	1.209	$24.18	$1,013.53
Charges freight and mill treatment, $6 per ton					252.00
Net					$ 761.63

From this is to be deducted the cost of haulage to the railroad or $18, leaving a profit of $743.53.

From the prospect trench and drifts, the following information was gleaned for future prospecting: Trench *A* showed no ore; neither did tunnel *D*; tunnels *B* and *C* opened a vein dipping 60 degrees, varying from 0 feet to 10 feet wide, and apparently 250 feet long between the two tunnels and extending some distance in the directions of *A* and *D*. The ore found assayed 1.209 ounces in gold per ton and this was sufficiently encouraging to warrant further prospecting, and owing to the flatness of the surface, trenches *E*, *F*, *G*, *H*, and *I* were started to cut the phonolite dike. Additional men were employed to push the work, and it was found that at *G*, where the basic dike comes in contact with the phonolite dike, there was a large vein of ore which was so favorable that it was decided to prospect the basic dike. No ore was discovered at *H*.

To excavate the five trenches required the labor of 5 men 20 days, and cost $630. On the basic dike, trenches *J*, *K*, *L*, *M*, *N*, *O*, *P* were cut, in all a length of 700 feet, that took up 47 days' time of 10 men and cost $1,495.

The assays derived from samples taken at *G*, *L*, and *M* were so favorable it was decided to prospect them deeper. At *G* the vein was followed down on the phonolite dike 60 feet in ore. Sinking was also carried on at *A*, *B*, and *C* in ore, and in all shafts at a depth of 60 feet on the dip levels were started.

The sinking was done by hand with the aid of a windlass and bucket, from which operation the following data were obtained.

Shafts 5 ft.×7 ft. required 12 holes per round, average $2\frac{1}{2}$ feet deep, drilled in 12.5 hours, $3\frac{1}{2}$ hours in two shifts were consumed in loading, firing, and cleaning up broken material.

On the first day two men drilled 30 feet of holes, which were loaded and fired. On the second day, two men loaded and hoisted for 3 hours, and were followed by two miners who drilled 25 feet of holes, which were loaded and fired. An average daily advance of 1 foot 7 inches was made in this way, and at every 6-foot advance a set of timbers was placed. It took 38 days to sink a shaft 60 feet in this way, and the cost which was $17.12 per foot was made up of the following items:

	Total Cost	Cost Per Foot	
Powder, caps, and fuse	$170.84	$ .95	
Labor (miners and muckers)	1,824.00	10.12	
Labor (blacksmith and bosses)	323.00	1.79	
Labor (timberman)	171.00	.95	$2.39
Timber	259.92	1.44	
Steel (depreciation)	9.36	.05	
Candles	26.45	.15	
Coke	98.60	.55	
Windlass, rope, and buckets	128.55	.72	
Shovels and picks	71.50	.40	
Total	$3,083.22	$17.12	
Eliminating windlass, rope, buckets, shovels, picks		1.12	
		$16.00	

Extra men were hired to drive the main drifts in 500 feet and make 7 cross-cuts averaging 15 feet. In *B* two drifts were carried 700 feet, and 9 cross-cuts, averaging 15 feet, were excavated. In *C* 4 drifts totaling 800 feet, and 8 cross-cuts, 25 feet each, furnished an advance of 1,000 feet. In all, 2,240 feet of drifting was accomplished. The estimation of 2,440 feet of track (using 12-pound rails at $47 per ton with fish-plates) is based on the cost per mile as follows: 364 pairs of splice bars; number of bolts, 1,456; weight of splice bars, .56 gross ton; weight of bolts, .15 gross ton; weight of spikes, .77 gross ton. Total weight of fastenings, 1.48 gross tons.

Weight of rails, 18.86 gross tons. Total weight of rails and fastenings, 20.34 gross tons per mile, then $\frac{2,440}{5,280}\times 20.34=9.4$ gross tons, at $47 = $441.80.

The 814 ties, spaced 3-foot centers, were 2 in.×4 in.×$2\frac{1}{2}$ ft., and cost $27.14.

In order to hasten the handling of broken rock and ore, and before drifting was commenced on the levels, three small electric hoists were purchased. This was necessary because the limit of a windlass is about 60 feet for economical work. The heaviest load to be hoisted at one time was estimated at 850 pounds, and hoisters were ordered capable of raising 1,000 pounds 200 feet in one minute, and motors having 8 horsepower were selected. The drums on the hoisters being 18 inches diameter, a $\frac{1}{2}$-inch steel wire rope was ordered with them.

It was found that 1 cubic yard of the Cripple Creek ore when broken occupied 1.73 cubic yards, also that while 12.4 cubic feet of solid ore weighed a ton, it took 21.5 cubic feet of loose ore to weigh a ton. The breccia is not as free drilling as granite, and sludge is made rapidly in drilling, however, the rock breaks better than granite. The number of tons of material excavated in driving the 2,440 linear feet of levels was:

$$\frac{2,440\times 7\times 5}{12.4}=6,890 \text{ tons}$$

In drifting, each man drilled 1 foot per hour, and with 11 holes in the face, each 28.5 inches deep, an advance of 22.5 inches was made each round. The material broken was ore and the amount to be handled was estimated to be as follows: $\frac{22.5''}{12''}\times 7'\times 5'=65.8$ cubic feet solid, or $65.8\times 1.73=113.8$ cubic feet broken ,per round. As each bucket holds 4.5 cubic feet, about 26 buckets will carry out the ore broken in one round. According to Gillette* one man can shovel 1.2 cubic yards per hour from the ground and 1.4 cubic yards per hour from steel, which gives one man 3.2 hours' time to shovel the material broken in one round. If 4 minutes' allowance is made for tramming and changing buckets per trip it will take one man 104 minutes to tram 26 buckets. From the above it is ascertained that an advance of 56.31 feet can be made in each drift per month, and that the 8 drifts are advanced $\frac{22.5''}{12''}\times 16$ hr. $=15.02$ ft. per day, consequently it will require $\frac{2,440}{15.02}=162$ days

*Gillette's Handbook of Cost Data.

to drive, hoist material, lay rails etc., making the cost of the work as itemized.

	Total Cost 2,440 Feet	Cost Per Foot	
Labor (drillers and muckers)	$15,552.00	$6.37	
Superintendence	1,377.00	.56	
Steel $ 164.75; Blacksmith and helper (labor) 1,296.00; Coke 420.19	1,880.94	.78	
Powder, fuse, and caps	2,062.78	.85	
Candles	300.67	.12	
Power	35.05	.01	$1.80
Hoistman	4,374.00	1.79	
Hammers $ 30.20; Steel plate 88.13; Rails, ties 468.94; Cars 192.00; Ore buckets 192.00	971.27	.40	
	$26,553.71	$10.88	
Leaving out cost of new steel and other supplies, and omitting depreciation	1,236.00		
Cost	$25,317.71	$10.37	
Cost (less supplies and less superintendence)		$9.81	

The appliances necessary for drifting and their cost are as follows:

Three head-frames (lumber)	$ 87.96
Three 24-inch sheaves and blocks	57.00
Three hoists	900.00
Three motors @ $230 f. o. b.	690.00
600 feet of ½-inch cast-steel rope	25.74
Freight on hoists 4,500 pounds at $.80 per 100	36.00
Freight on motors, 2,400 pounds at $1.75 per 100	42.00
Freight on sheaves, 360 pounds at $.65 per 100	2.34
Freight on rope, 234 pounds at $.55 per 100	1.29
Total	$1,842.33

The following points have been determined by the prospecting:

Shoot	Length Feet	Width Feet	Average Width Feet	Average Value
A	500	0–12	3	$15.00
B	700	0–10	3	$13.00
C	300	0–14	16	$20.00

Shoot *A* dips 50 degrees with the basic dike to the east; shoot *B*, 60 degrees with the phonolite to the west. At *C*, the junction of the two dikes, and the general dip of ore body is found to be at an angle of 22 degrees 42 minutes. The prospect shaft at *G* on shoot *C*, going down on the ore body which lies in the dip of the phonolite dike (60 degrees) runs into barren rock at a depth of 60 feet, though the drifts still show ore for 300 feet along each dike, the richest ore is at the intersection of these dikes, 150 feet from the foot of the shaft.

To continue the development work a winze was sunk from the first level (60 feet) at the end of the drifts, and at 126 feet the winze passed into barren rock, having passed through the intersection of the two dikes and finding ore the length of the winze.

The vertical distance down, now 176 feet, gives 514 feet along the intersection, and indicates 206 feet of backs of probable ore, 300 feet long, on 60 degrees or phonolite dike, and 231.5 feet of backs of probable ore, 300 feet long on the 50 degrees or basic dike. There are moreover, 60 feet and 69 feet, respectively, of backs of blocked out and proved ore, less 17.3 feet and 19.8 feet, respectively, to compensate for soil 15 feet.

The ore is estimated as follows:

$$\frac{[300\times(60-17.3)\times 16]+[300\times(69-19.8)\times 16]}{12.4}$$

$$=\frac{205,000+230,000}{12.4}=\frac{441,000}{12.4}=35,500 \text{ tons (proved and blocked}$$

out) above 60-foot level.

$$\left(\frac{300\times 126\times 16}{2}\times\frac{1}{24}\right)+300\times 82\times 16\times\frac{1}{24}=56,100 \text{ tons blocked}$$

out below 60-foot level.

$$35,500+56,100=91,600$$

$$\frac{(300\times 206-17.3\times 16)+[300\times(231.5-19.8)\times 16]}{12.4}$$

$$=\frac{906,000+1,015,000}{12.4}=\frac{1,920,000}{12.4}=154,900 \text{ tons,}$$

total blocked out and partly blocked out, including above 91,600.

$$\frac{(300\times 146\times 16)+(300\times 162.5\times 16)}{12.4}$$

$$=\frac{700,000+780,000}{12.4}=\frac{1,480,000}{12.4}=119,400 \text{ tons}$$

(probable ore between first and second levels).

This condition requires that 200 tons of ore be mined per day, which is a little under the operations of the Portland Gold Mining Co., but a good average production.

200 tons a day for 18 months or 540 days = 108,000 tons.

Allowing 10 per cent. for pillars, the 154,900 tons (blocked out) would give 139,410 tons.

The Portland Gold Mining Co. has produced its gold at a cost of 70 per cent. per ounce, and a profit of 30 per cent. per ounce. (The value per ton has been above 1 ounce, however.) The 91,600 tons of ore blocked out and carrying 1 ounce per ton, at a profit of 30 per cent. per ton, anticipates a profit of $\frac{(91,600\times \$20.6718\times 3)}{100}=\$56,801.16$, and 139,410 tons would give a profit of $(139,410\times \$6.20)=\$864.342$.

Whether this ore can be mined in time to make $864,342 a paying investment on the money invested; and also to find if the ore can be produced at a profit of $6.20 per ton, are two items for consideration.

The data collected during the operation of sinking the winze 126 feet with the help of one of the electric hoists placed on the 60-foot level, give the cost of the winze as follows:

Cost of Winze

Two men day shift, 80 shifts, at $4	$ 640.00
Two men night shift, 80 shifts, at $4	640.00
One hoistman and timberman, day shift, 80 shifts, at $4.50	360.00
One boss, hoistman, and blacksmith, day shift, 80 shifts, at $4.50	360.00
Powder, 12 holes, 80 rounds, 960 holes, each hole 2½ sticks (.625 pound.), 600 pounds, at $.155	93.00
Caps, 960 holes, at $.85 per 100	8.16
Fuse, 960 × 7 ft. = 6,720 feet, at $.65 per 100 feet	43.68
Candles, 1,914 at $.0145	27.76
Timber, 72 bd. feet per foot of shaft, 9,072 bd. feet, at $20 per thousand	181.44
Coke for blacksmith, 5 tons at $20.75	103.75
Power, 1.186 horsepower + .303 = 1.489 horsepower per minute used every 1¾ minutes, or 2.5 horsepower hours every hour, say used 8 hours out of 16 hours, 20 horsepower hours per day. Total, 80 days, 1,200 kilowatt hours, at $.013	15.60
Total, for 126 feet	$2,473.39
Cost per foot	$19.64

Most of the figures making up the cost sheets are Cripple Creek figures, including freight, etc. There were, however, 28,303.55 pounds of material bought in Denver, which cost $.65 per 100 pounds, and 2,044 pounds of freight at $.75 per 100 pounds, the total costing $199.30.

Expenditure for Prospecting

Surface prospecting	$ 3,505.37	
Underground prospecting	33,952.65	$37,458.02
Additional freight charges		199.30
Total		$37,657.32

Time occupied in surface prospecting was 100 days, and in underground prospecting 280 days, a total of 380, or 1 year 15 days.

During prospecting, ore was shipped almost from grass roots.

On shoot *A*, 45 feet of shaft and 500 feet of drifts were in ore. The ore in the shaft averaged 5 ounces gold per ton,

and in the 700 feet of drifts, the average was .725 ounce. The average width of the shoot was 3 feet.

On shoot *B*, the ore in the 45 feet of shaft ran 4 ounces in gold per ton, and the 700 feet of drifts averaged .628 ounce gold. The average width of the shoot was 3 feet.

On shoot *C*, 45 feet of shaft averaged 6 ounces of gold, going as high as 8 ounces; on the 60-foot level 600 feet of drifts averaged 1½ ounces, and in the 125-foot winze averaged 2 ounces. The width of the shoot averaged 16 feet.

Smelter returns for ore shipments I and V are given to show the forms used.

Shipment I, to U. S. R. & R. Co., at Colorado City
(Payment at rate of $20 per ounce)

Gross Weight Tons	Moisture Per Cent.	Net Weight Tons	Assay *Au* Ounces	Value Per Ton	Total Value
43.9	4	42.144	5.000	$100.00	$4,214.40
Freight and treatment, $8.50 per ton..................					373.15
					$3,840.25

Shipment V, to A. S. & R. Co., at Denver
(Payment at rate of $19.50 per ounce)

Gross Weight Tons	Moisture Per Cent.	Net Weight Tons	Assay *Au* Ounces	Value Per Ton	Total Value
976.0	4	936.96	5.000	$117.00	$109,624.32
Freight and treatment, $5.50 per ton..................					5,368.00
					$104,256.32

Receipts From Ore Sales

Shipment I,	$ 3,840.25	532.9 tons from *A*.		
Shipment II,	4,361.88			
Shipment III,	2,998.37	727.9 tons from *B*.		
Shipment IV,	4,827.40			
Shipment VI,	1,992.72	1,063.4 tons from *C*.		
Shipment V,	104,256.32			
Less hauling to railroad, 2,324.2 tons, or 1,850 cubic yards, in 1-yard wagons, 1 hour per trip, 1,850 trips; equivalent to 1 team and driver, 231 days, at $6..			$1,386.00	
Less umpire assaying, 930 assays, at three for $1..............................			310.00	
			$1,696.00	
Net receipts......................................				$120,580.94
Receipts of ore sales in prospect tunnels............				743.53
Total receipts ore sales............................				$121,324.47
Cost of prospecting................................				37,657.32
Cash on hand................................				$83,667.15

Plans are drawn for an incline shaft to follow the intersection of the dikes in the foot-wall. All work has been stopped on the shoots *A* and *B*; one hoist is used in the sinking of the incline shaft, while one is still used to take ore out of the prospect hole and to continue the exploration work.

It is assumed that, by the time the incline shaft has reached the first level, the plan for the surface buildings will be finished and their cost estimated, and that by the time the shaft has reached the second level, the contract will be let for the surface structures, and all mining equipment. This gives 210 days for surface buildings to be built and machinery to arrive while drifts and raises are being driven.

TAYABAS PETROLEUM

A sample of crude petroleum, typical of that found in the Tayabas Province, P. I., resembled Pennsylvania petroleum in containing a fairly high proportion of volatile hydrocarbons, in having a paraffin base and in being free from sulphur. The proportion of volatile constituents boiling below 150° C. was greater than in most petroleum oils: Sp. Gr. .831, initial boiling point 70° C.; first fraction (light oils) 70° to 150° C., 36.5 per cent.; second fraction (burning oils) 150° to 300° C., 48.75 per cent.; and residue, above 300° C. (by difference) 14.75 per cent. It contained 30 per cent. of unsaturated hydrocarbons which could be removed by acid. It might be described as essentially a paraffin petroleum. G. F. Richmond. (Philippine Jour. of Sci., v, I.)

DRIFTING WITH A STOPING DRILL

*By H. E. Moon**

It is interesting to note the ingenuity displayed by some miners, especially those who are leasing, in keeping down operating and equipment costs.

An example of this recently came to the writer's attention in the Cripple Creek district of Colorado. Two miners had a lease on one of the lower levels of the Granite mine. Their work was entirely stoping and raising, and their drill equipment consisted of air-feed stoping drills.

They drove the raises *A* and *B*, Fig. 1. Owing to heat and bad air and also to assist in opening the stope, they decided to drive the drift *C* from *A* to *B*, thus giving a chance for ventilation. They could not afford to purchase a drifting drill, but with the aid of a simple foot-plate they found that they could use a stoping drill to put in holes at all angles from the vertical to the horizontal. In one case they put in a hole 5 feet deep which dipped about 4 inches below the horizontal in that distance.

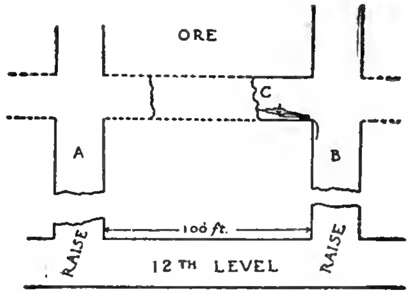

Fig. 1

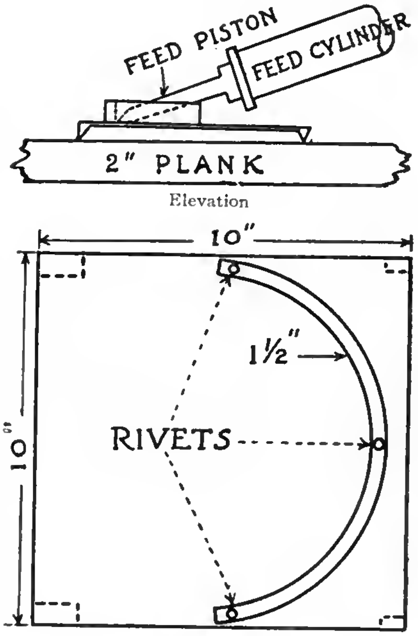
This foot-plate, Fig. 2, was made of a sheet of ⅜-inch steel with ears turned down at the corners to act as spikes and hold the plate on to a plank. To this plate was riveted a piece of angle iron bent to a **U** shape.



Plan

Fig. 2

The drill used for this work was the new Sullivan stoper. The ground was a hard granite. The cutting speed was from 14 inches a minute, in vertical holes, to 8 inches a minute in horizontal holes. A blowpipe was connected with the air supply and used to clean the cuttings from flat holes.

[Sullivan stope drills are in use in the anthracite coal fields of Pennsylvania for work like that described above, for driving short tunnel headings. In this instance, hand-feed hammer drills are used to drill down holes in the face. The rock next the tunnel floor is then shot out, and the stoper used to drill upper holes.—Ed.]

BLAIR'S ZINC-LEAD PIGMENT PLANT

Written for Mines and Minerals, by J. I. Blair

Before entering into a description of this plant attention is called to the principal considerations governing the design and construction. In this particular case the plant was intended as an addition to a regular lead smelter in order to treat the flue dust, blue fume, and a partly roasted complex zinc-lead ore that is common throughout the Western States.

A Plant Used in Addition to a Lead Smelter to Treat Flue Dust and Partly Roasted Ores

The capacity of the plant is to be approximately 144,000 pounds per day of 24 hours, of the material just mentioned and it is estimated that about 48,000 pounds of coal will be required per day. The word estimated is used because there has been introduced some carefully calculated data in the design of certain parts of this plant, although in the main it is the result of the experience in connection with sublimed lead and zinc oxide plants.

In the first design an attempt was made to take the hot fume from the trail coming from the blast furnaces and open hearths and, by drawing it through either an incandescent bed of coke or through an electric arc with the sulphurous fumes from the roasters, convert the fume directly into the desired white pigment. In this case the blue bag room would be converted into the white bag room and the cost of the plant would be probably 70 per cent. less than the cost of the regular plant as here outlined. The belief was that such a plan could be carried out successfully, from the fact that the fume in the "trail" of a lead smelter in the Middle States settled near the bag house in distinct layers, each one a fractional part of an inch thick, and throughout the bed of some 4 feet in thickness it was found that there were several layers of a relatively white fume between layers of lead-gray fume and blue dust. This arrangement showed that at some time during the smelting the conditions were realized for the formation of white fume. While it is to be hoped such a plant may become a reality, it has been decided that the better plan to follow, at least for the present, is the installation of the plant here described.

It has been claimed by experienced men in the sublimination of lead and zinc that it is practically impossible to produce the white fume from the blue fume alone. However, experiments show that if the requisite sulphur is added at the right time, basic sulphate will be obtained.

Another solution to the problem, that of briquetting the flue dust, was adopted by the St. Louis Smelting and Refining Co. with the result that only about 40 per cent. of the flue dust and blue fume was eliminated. The briquets were made, using the fluxes, lime or cement, as binders.

Fig. 1 shows the plan and side elevation of the zinc-lead pigment plant. To the left, not shown in the illustration, the coal bin is arranged, consisting of a simple shed and a floor made from the lumber that was used for scaffolding.

The railroad track at the coal bin is given a light grade and extends between 200 and 300 feet beyond the plant. The loaded cars are placed at the far end of the track and dropped down to the bin to be unloaded.

In choosing the type of furnace shown in Fig. 2, the considerations were first cost, cost of up-keep, and working costs. The slag-eye furnace although more compact is capable of treating more material and has the advantage of lower first cost than the furnace chosen, but has proved a troublesome furnace to run and requires considerably more skill in the furnace men to operate it properly. The blast necessary in this type of furnace is too great to be handled by a simple fireclay lined conduit here shown. Furthermore, the pigment is fused, choking up the mouth of the furnace and filling the conduit near the furnaces, making a shut-down, clean-out, and rebuilding of the combustion chamber imperative every few months.

For the small plant considered wheelbarrows are employed, and the charging is done by hand; for a large plant, a system of tram tracks override the plant and the charging is automatic from an overhead tram. The principal disadvantage of the furnaces shown in Fig. 1 is that considerable time and work is required to remove the clinker which remains on the grate after each heat. This source of loss could be reduced by using a movable grate bar worked by means of a lever, thus loosening the clinker and allowing it to drop into the pit below the grate, where it could be easily removed after the furnace has been recharged and in operation. The total grate area is 758 square feet, or 1 square foot per 1.5 pounds coal per charge of 4.5 pounds of material.

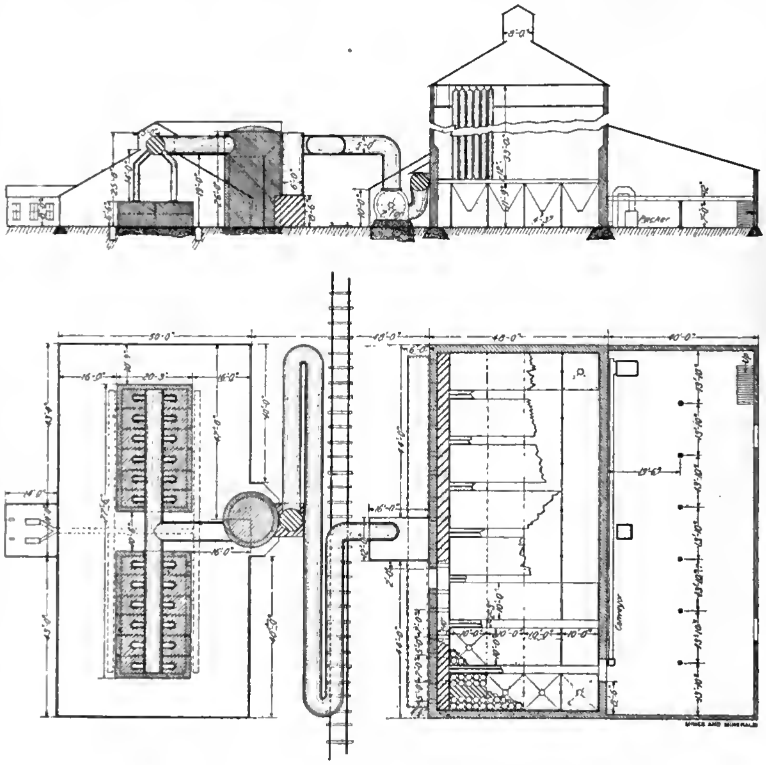

Fig. 1. Plan and Elevation of Zinc-Lead Pigment Plant

The vertical conduits directly over the furnaces are provided with "butterfly" valves (not shown in the drawing). These valves, which are opened during cleaning operations, are lined with a good fireclay. The conduits are made in sections so a burnt section can be removed and a new one inserted in a relatively short time. The size of the conduits is such that with the draft used the pigment and ash will be kept in suspension until they reach the tower, Fig. 3, where the heavy substances will drop out. From here the fume is kept in suspension until it reaches the large supply pipe situated along the side of the bag-house where, owing to the increase in volume and lower temperature, the remaining heavy ash and dust will fall into the short bags which are suspended from thimbles along the under side of the supply pipe (not shown in drawing), leaving the pure fume to enter the bags. This style of conduit has the advantage over a set of goosenecks, in lower cost and greater efficiency. It costs less because it is much simpler in design and requires less material. It is more efficient because of its horizontal position which admits of a greater area exposed to the cool atmosphere while with the goosenecks the heated vapor rises from the top of the hopper and from around the base of the

gooseneck and keeps the upper parts of the goosenecks surrounded with hot air, thus reducing the efficiency of their cooling effect. The overhead feature shown in the illustration makes it possible to use the ground beneath for other purposes. Thus the space occupied is reduced to a minimum. Small doors are provided along the conduit to admit air in order to regulate the temperature and velocity as occasion may require.

In determining the length of the conduit, calculations have been based on a study of the efficiency and properties of the larger type—600 feet—at Coffeyville, Kans., and also of the shortest—400 feet—at the new addition at Joplin, Mo., neither of which have given good results. The long trails cause too much pigment to settle out before it reaches the bags, while the short one burns up the bags and produces an inferior quality of pigment. With the increase in efficiency due to the peculiar arrangement of the conduit shown it is estimated that the 435-foot connection with the very low blast pressure adopted is about the length needed to furnish the desired results provided the exhaust fan is properly regulated. This, however, can be exactly determined only by actual operation.

By having the inlet to the tower on one side the inflowing gases swirl around the inclined walls and permit the heavier particles of ash to settle. The outlet to the tower is an arch. The tower is to be cleaned out each day during the shut-down for the bag shaking.

In designing the bag room it would have been optional whether the fume entered by way of the top by means of a set of pipes with thimbles and suspended bags as in the eastern oxide plants or through hoppers at the bottom, were it not for the quantity of sulphur gas evolved during the treatment of sulphide ores. The corrosive action of this gas on steel and iron work regardless of the protective coatings makes it advisable to use wood wherever possible, as it seems better adapted to the process than other materials. Each hopper is provided with a short sack to collect the pigment as it is shaken down. This is an improvement over the method of closing the mouth of the hopper in general use at some of the plants, which causes the pigment to cake and become lodged, and requires the men to pound on the hopper with pieces of wood to loosen and to cause it to drop. Treatment of this kind generally causes leaks in the riveted seams of the hopper. The suspended bags increase the filtering area of the bag room about 11 per cent. and to remove the pigment one has only to loosen the bag and replace it with an empty one.

Each row of hoppers is provided with a damper, making it possible to shut down a row during the repair of burnt bags. There is a suspended walk overhead where the bags may be tied, and a lower plank walk between the hoppers, shown in the illustration. Altogether there are 640 woolen bags 30 feet long by 20 inches diameter suspended by small ropes about 15 feet long, which permit of the bags being lowered as they are scorched and burned off around the thimbles. The total filtering area of the bags is 117,150 square feet, or 154.5 square feet per square foot of firegrate area. There are as few openings in the bag room as is possible, for light. This arrangement causes the ascension of the gases thereby creating a draft, which is very desirable. The white color of the pigment makes it possible to see how to get around with but little outside light. Openings in the room would permit the pigment to be blown out of the buildings by cross-currents of air, and considerable loss sustained.

It is surprising to know how far this fume will be carried in the air. Several samples of surface dirt at various places and at varying distances from the Pitcher Lead plant showed that the fume traveled many miles. The loss in this manner is almost beyond belief, thousands of pounds having escaped before it was suspected.

Adjoining the bag room is the packing room and cooperage, in which the screw conveyer is the most important feature. This conveyer is in a trough 10 inches square along the side of the partition wall. The conveyer blades do not fit the box but leave a space at each corner. There is a square section 2 in. × 2 in. removed from the outer edge of the blades which causes the revolving screw to mix as well as convey. The blades also work the air out of the pigment, making it possible to pack it by machine.

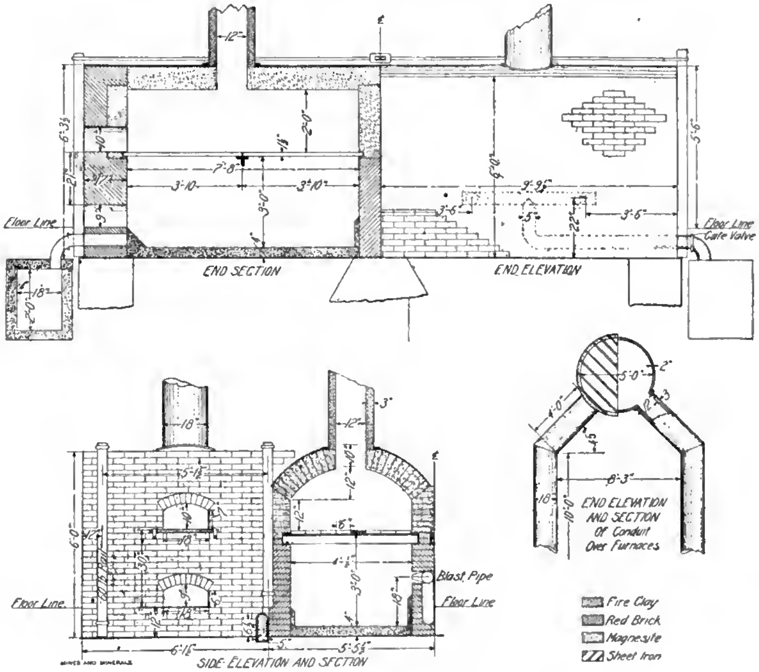

FIG. 2. FURNACE AT PIGMENT PLANT

The room over the packing department may be used as a cooperage, carpenter shop, "tailor shop," and storeroom for supplies. One or two men are kept busy repairing bags.

The switch between these rooms and the warehouse is up grade, to permit the cars to be moved by gravity to the concrete loading platform which is on a level with the car door.

The quantity of blast must be regulated to comport with the composition of the charge. For an ordinary charge using a coal containing 70 per cent. carbon the air necessary would be about 140 cubic feet per pound coal, or a total of $12{,}000 \times 140 = 1{,}680{,}000$ cubic foot per furnace. This for 24 furnaces would be 40,320,000 cubic feet of air for fuel combustion. For a charge carrying 45 per cent. lead, each pound of lead would require $.0168 \times 36{,}000 = 604.8$ cubic feet of air for the formation of the basic sulphate (the sulphur present goes to form the sulphate), a total of 40,320,604 cubic feet of air required per 5 hours, or 300 minutes = 134,402 cubic feet of air per minute.

This blast is delivered at from 1- to 2-ounce pressure by two No. 5 blower fans. The blast is kept underground, as shown in Fig. 1.

The 6-foot exhaust fan is driven by an electric motor with a resistance to regulate the speed between 150 to 250 revolutions per minute, depending principally on the outdoor temperature. As a rule the cooler the air is the faster the fan is driven.

The location for this fan was governed by the results of a practical demonstration which was carried out at a lead smelter in Collinsville, Ill. At first the fan was erected near the furnace, then it was moved about 100 feet toward the bag house, next it was moved to about three-quarters of the distance from the furnace to the bag house and finally it was set up at the bag house, where it gave satisfactory results for the first time.

The steel work for the trail and bag room can be put up for $15,000 according to the estimates of J. H. Blair, engineer, South Western Bridge Co.

In calculating the extra load for roof truss over bag room the bags are estimated to weigh 75 pounds each.

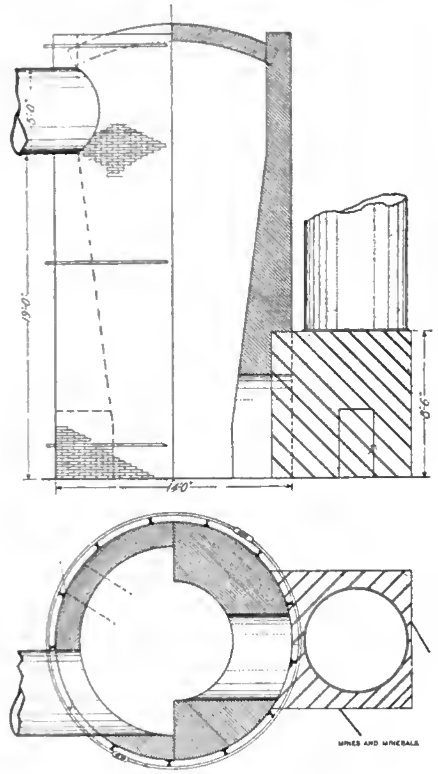

Fig. 3. Plan and Elevation of Tower

A general bill of material for a 50-ton-capacity plant is as follows: 700,000 brick; 35 cars crushed stone; 37 cars sand; 15 cars cement; 3 cars lime; 2 cars lumber; 800 bags, $5,200; 20,000 feet corrugated iron.

METAL MINING FATALITIES IN IDAHO

To those who have through experience become conversant with the difficulty of obtaining satisfactory statistics as to fatalities in metal mines, the recently issued report on the metal-mining industry of Idaho for 1910, by Mr. F. Cushing Moore, state mine inspector, will prove welcome.

The death rate for the past 8 years, the period covered by Mr. Moore's statistics, is remarkably low, but 2.487 per thousand employes. This compares favorably with the fatality rate of 2.45 in such old established coal-mining states as Pennsylvania and is a much better showing than that made by the coal mines of North America as a whole, 3.11 per thousand. It is also far better than the average (3.14 per thousand) for the metal mines of North America exclusive of Mexico as reported by the committee of the American Mining Congress to the Los Angeles convention.

We quote that portion of Mr. Moore's report bearing upon the subject in question: "The mining industry in the state for the past year, has been very fortunate, in that very few fatal accidents have occurred. The most prevalent cause of accident was that of falling rock in the working faces, of which there were seven fatal accidents, or about one for 1,000 miners employed. Explosions of blasting compounds was responsible for two deaths and two men were killed by falling down chutes or raises, another death was caused by contact with a high tension electric wire used in transmitting power to the underground workings. This, however, is a very creditable showing and is due to the persistent efforts on the part of the mine operator to caution the underground worker to protect himself, as the vast majority of accidents are due to the carelessness of the injured.

"The accompanying table shows the number of fatal accidents with the causes for the same, since the first of the year 1903; prior to that time no record of fatal accidents was kept in this office."

The above table emphasizes the fact that accidents are very largely unavoidale at times, for during the year 1908 only 10 accidents occurred, while there were 19 during 1909, and again during 1910 only 11, but as 10 of the 19 accidents in 1909 were due to falling ground, it appears that it is negligence on the part of the miners themselves, rather than upon the mining operators, as the same precautions were taken each year. This point cannot be too strongly emphasized, for no matter how careful a company may insist upon the back being examined, prior to the time the shift goes on, by the time that several holes have been drilled by a machine, other rocks have been shaken loose and only constant watching by the men at the breast can prevent fatal accidents.

COALING STATION IN SOUTHERN PACIFIC

The Campagnie Francaise des Phosphates de l'Oceanie has organized a coaling station at Tahiti, Society Islands, and is prepared to furnish coal to all war or merchant ships calling there. A 3-masted bark is used as a depot and is permanently anchored in 9½ fathoms of water in the harbor, where coal may be loaded from either side to other vessels at the rate of 300 tons a day. The stock will be 2,500 to 3,500 tons, to be increased according to demand, and is from Southern Australia, being "the best screened large coal." The prices will be $9 to $11 a ton, influenced by varying market prices and freight rates.

Fatalities in Idaho

Cause	1903	1904	1905	1906	1907	1908	1909	1910	For 8-Year Period	Percentage of Total Accidents for 8-Year Period
Fall of rock from working faces	4	3	5	4	5	4	10	7	42	33.33
Explosion of blasting compounds	7	5	5	6	2	1	2	2	30	23.81
Falling down chutes, raises, and other openings	3	1	3	4	7	1	4	2	25	19.84
Hoisting accidents—bucket, cage, or skip	3		2			1	1		7	5.56
Electrocution by contact with live wire			2		1	1	1	1	6	4.77
Car accidents			1	1	1	2	1		6	4.77
Tapping old workings	1	1			2				4	3.17
Caving bank in placer mine	1		1						2	1.59
Suffocation from gas or smoke	1								1	.79
Accidents from handling timber				1					1	.79
Falling staging while drilling				1					1	.79

Total	20	10	20	17	18	10	19	12	126	100.00
Average number employes	7,000	6,000	6,000	7,000	7,000	5,500	6,000	6,000	6,312	
Fatalities per 1,000 employes	2.85	1.66	3.33	2.42	2.55	1.75	3.33	2.00	2.487	

THE PORCUPINE GOLD FIELDS

*Written for Mines and Minerals, by Ralph A. Meyer, E. M., B. Sc.**

Until the last two or three years the Porcupine area was difficult of access and little prospecting was done on it. The information concerning it was practically all contained in the reports published by the geologists who accompanied Ontario Land Surveyor Niven in his base line work and the township surveyors in the years 1896 to 1899—1903 to 1905.

Districts of Nipissing and Sudbury, Ontario. Location and Geology

The first real prospecting in the area seems to have been performed in 1906 on the Wilson claim now known as part of the "Timmins" mine.

In 1909, during the month of June, interest was revived in the district by numerous discoveries having been made, following which the Government had an abstract report and brief examination made by Mr. James Bartlett, one of the Bureau's geologists.

From 1909 to present date, much enthusiasm has been displayed, approximately 10,000 claims having been staked.

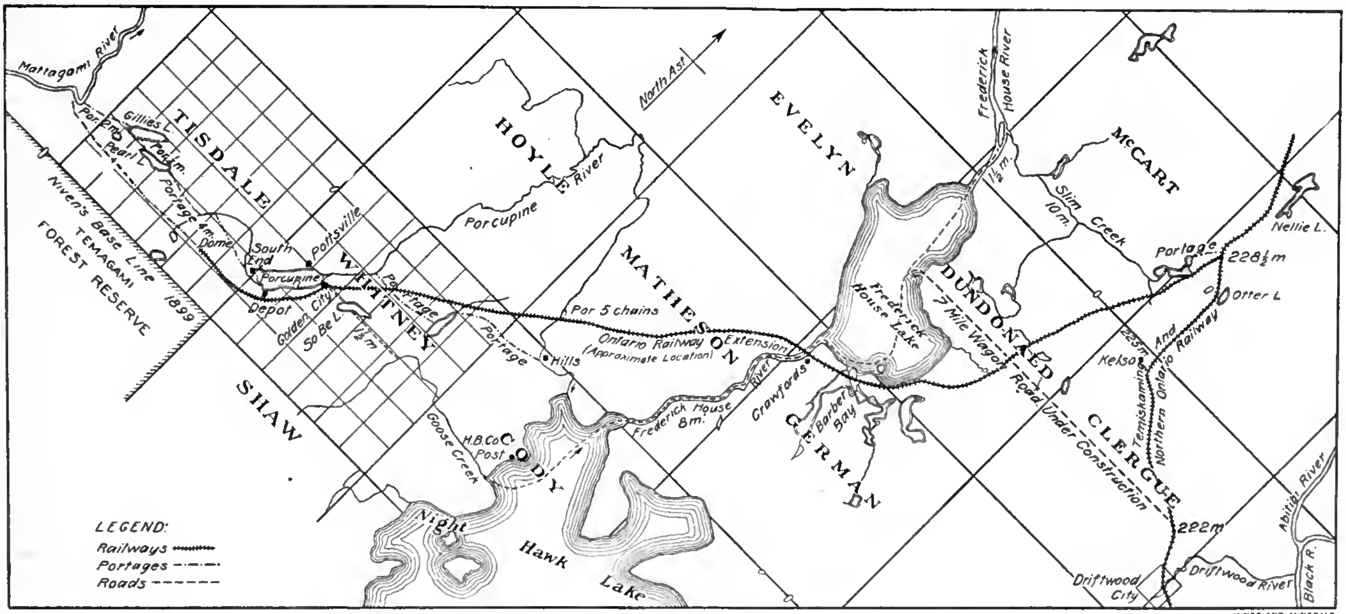
The tonnage will be obtained from the sulphide deposits, and even at the present early life of the camp, all indications point to a large tonnage. As a proof of such indications, both the Dome and the Timmins properties are installing mills of 40 and 30 stamps, respectively, equivalent to a daily capacity of approximately 350 tons.

Several of the smaller properties, as well as those that are in earliest stages of development, have or are installing small units, such as two Nissen stamps.

It is predicted that certain sections in the Porcupine area will contain free-milling ore that will make history in gold mining in the North American continent.

To reach the Porcupine gold camp, go to Kelso, on the Temiskaming and Northern Ontario Railway. From this point the balance of the journey is performed by driving; the total distance being 34 miles. This is known as the winter route. During the summer and spring months, the journey is performed by means of driving and launches.

The first portion of the journey, on leaving Kelso, is covered by a 12-mile drive which is subdivided into 7 miles on a fairly good government wagon road, and 5 miles along the shore of Frederick House Lake, on a gravel bed, to what is known as



Map of Porcupine Region

The greater amount of development work has been performed in the Township of Tisdale on the Timmins, Dome, Foster, Vipond, Crown Chartered, Armstrong-Gibbon properties, etc. There are also several properties located in the adjoining townships of Whitney, Shaw, Deloro (formerly known as the Temagami Reserve) Carmen, Langmuir, El Dorado, Denton, where phenomenally rich surface showings have been discovered and in which claims have been purchased and are at the present time being actively developed and prospected.

At the present time the general public is of the opinion that all the "pickings of the pie" are located in the Township of Tisdale. It does not follow because the Ontario Government has decided that each individual township shall be surveyed into 6 miles square that all mineral occurrences should cease within the near approach of a concession line. The uninitiated are prone to regard these concession lines as stone walls that cut off everything.

The general public should not be too easily captivated by spectacular free gold showings, as these alone do not convey much more than that the country is gold bearing.

Crawford's Stopping Place, located at the junction of Frederick House Lake and the Frederick House River. At this point the journey is covered by means of gasoline launches up the Frederick House River, across Night Hawk Lake in a northwesterly direction to what is known as Hills, a total distance approximating 14 miles. From the latter mentioned point, the balance is covered by driving on the government road to Porcupine townsite, better known as Golden City, a distance of 8 miles.

Both in the summer and in the winter, the journey from Kelso to Porcupine can be made in a day, and in fact in the winter season it takes a considerably shorter time, the entire distance being traversed by sleighs.

The Ontario Government is at the present time extending the railway from Kelso to Porcupine, in fact, 8.5 miles of the steel is already laid and the government expects to have the entire track installed by the end of June of this year.

Since the government has taken these steps, the camp has gained stimulus and prestige.

The railroad was advised by several geologists attached to the Bureau of Mines and by some of the most reputable engineers, such as William Frechevill, of the Anglo-French Exploration Syndicate; Louis Webb, of the South African Consolidated;

*Camborne School of Mines, Cornwall, England, and Royal School of Mines, Freiberg, Saxony, Germany.

W. J. Loring, of Bewick, Moering & Co.; Doctor Simon, representing French capital; and others.

Under present conditions one is able to leave New York and arrive at Kelso, within 34 miles of the camp, in a Pullman car, the journey being completed within 1½ days.

Such easy access to a gold camp from the large centers such as New York, Chicago, Pittsburg, Boston, and Toronto, has never been known before. This is very important to those who invest appreciable sums of money in gold mining as they are in the position to visit and keep in touch with their investments more satisfactorily than if their headquarters were located a thousand miles or more from the seat of operations.

There are three recognized townsites, located on Porcupine Lake, which is approximately 2 miles long, ½ mile in width, the elevation being 913 feet above sea level.

The townsite, known as the Provincial Townsite or Golden City, is situated at the extreme north of Porcupine Lake; that known as Porcupine Townsite, where the greatest amount of activity has been displayed, is located at the extreme northwest of the lake.

Since the location of the railway has been definitely decided, there is no doubt that the provincial townsite and the one at the extreme south end of the lake will be the most active, as there will be a depot at each townsite.

The recorder's office is located at Golden City in addition to several stores, etc.

A post office and hotel, known as the "Shuniah," also two banks are located on Porcupine townsite.

Three other hotels are under construction in addition to a post office and theater at the south end townsite.

There are five banks already in the camp.

The townsites are all on flat land partly composed of "muskes" (a local term designating swampy ground) and are connected with the outside world by telephone, two lines having been installed; one to Kelso and the other to Matheson. The former is operated chiefly for local calls, and the latter is used mainly for the transferring telegraphs.

At the present stage the properties generate their own power, but such will not be the case nine months hence, as a syndicate has leased the Sandy Falls, situated on the Mattagami River, in the Township of Mountjoy, distance 6 miles approximately from the main center of active operations.

The syndicate intends to generate 3,000 horsepower, which will adequately supply the electric energy as well as motive power for compressed air for the entire camp, so far as discovered up to date.

The greater part of the surface is low and wet, and this has hampered prospecting considerably during the past summer, but it does not signify that because a claim is situated in low ground it is worthless, for since the freeze-up, approximately one dozen most valuable discoveries have been made in the so-called swamps.

In other words, what is looked upon as swamp, is nothing more than the surface drainage from the surrounding outcropping ridges. There is no doubt that as soon as mining operations are in full swing the swamps will become drained. The lower flat surface is occupied by a banded clay, together with some sand and gravel. Overlying the clay is a layer of vegetable mold from a few inches to a foot or more in thickness.

Outcrops of compact rock occur irregularly over the surface covering, somewhat resembling the undulated surface of a calm sea.

Some of the outcroppings are small and difficult to locate; in other sections of the area the rocks rise into ridges, which extend across several claims.

In the majority of cases the rocks do not rise to a greater height above the general level than 50 feet, and it is exceptional that they rise to heights of 100 to 150 feet. The area lying between the mouth of Porcupine River and Porcupine Lake has a maximum elevation of about 970 feet; the southwestern portion of Tisdale is considerably higher, reaching an elevation of 1,000 feet.

The lakes are narrow and the rivers have cut deep.

The greatest depth of Porcupine Lake has been found to be 20 feet.

The oldest series, the Keewatin, is similar to rocks of this age found in various parts of the Province of Ontario from the Quebec boundary on the east to that of Manitoba on the west.

The series is here much more disturbed than it is in the Cobalt area, as is evidenced by its schistose appearance.

In the Porcupine area, some of the Keewatin rocks have escaped metamorphism sufficiently to show their general character. Most of the Keewatin in the Porcupine area, as elsewhere, consists of dark-colored or greenish schistose rocks of basic composition.

Quartz porphyry is however a quite common rock in the Porcupine area.

While it occurs in dikes it is also found in large masses. Associated with the Keewatin, especially in the southern part of the township of Whitney and southeastern portion of Shaw, there is an iron formation known as "jaspeylite," consisting of thin alternate bands of magnetite and silica. In certain instances the Keewatin rocks contain considerable calcite and dolomite.

A belt of Huronian fragmental rocks outcrops at intervals across the northern part of Whitney township and southwest through Tisdale township. The Huronian has been subjected to metamorphism and in instances has been rendered highly schistose.

Several dikes of olivine diabase, cutting the Keewatin, have been found in the area; also serpentine and sericite schists, which are mostly associated with the quartz porphyry and rhyolites. Some of the schists are impregnated with iron pyrites and ferruginous dolomite, which at the surface cause the rocks to weather to a rusty brown. The general strike of the schist is northeast and southwest. There is pronounced evidence of glacial action over the entire area.

Numerous outcrops of quartz are found both in the Keewatin and Huronian rocks. The age of the rocks does not seem to have any bearing on the vein either as to form or to gold contents. There is little doubt that the quartz deposits of the Porcupine area are connected with the great granite intrusions which took place in post-lower Huronian times. The quartz has been deposited from the impure waters, highly heated and under great pressure, which worked through the rocks after the granite intrusion.

The quartz veins vary in width from a few inches to 30 and 40 feet, the average width being from 3 to 4 feet. In many instances the ore bodies cross the strike of the schist, and in such cases they vary in width from point to point. In individual cases masses of quartz from 75 feet to 100 feet in width are rich in free gold.

A feature worthy of note is the persistency of the veins, which in the majority of cases can be traced for hundreds of feet, and in individual cases for thousands of feet.

The area over which these gold-bearing veins occur covers approximately 50 square miles, and each day reliable information is being received relative to gold discoveries made north, west, and southeast of the present center of operations.

Visible gold is seen at numerous points in the large masses of quartz and is associated chiefly with iron pyrite, arsenical pyrite, galena, zinc blende and small quantities of copper pyrite.

The schist near the veins is impregnated with iron pyrite and in many cases assays high in gold.

In South Whitney and southeast Shaw townships, deposits of iron pyrite occur, which carry gold. Samples from one of these sulphide deposits assayed $20.20, $34.80, and $80 in gold. It must be understood however that these figures were obtained from surface samples which had become enriched by oxidation and concentration to an average depth of 4½ feet.

Two pits were sunk to a depth of 9 feet and after systematic sampling of the vein which was 12 feet and 22 feet wide in the pits, respectively, an average assay of $7.50 was obtained.

It would appear that originally the iron pyrite and other associated sulphides were the "mother parent" and are the true gold carriers. Such can be assumed from the following reasoning: The chemical composition of iron pyrite is FeS_2. Where the FeS_2 comes in contact with certain mineral solutions, or the ordinary physical elements, the sulphides become changed to sulphites and thiosulphites, and a small proportion into sulphates. The sulphites are soluble and in turn are washed away. The iron becomes oxidized and forms the reddish-brown oxide or gossan. Any insoluble matter or elements that are unattacked by the above-mentioned agencies are left behind in the free state, which is in this particular case gold.

Note.—A small amount of gold is dissolved due to the presence of a certain percentage of iron sulphate.

There is little doubt but that the quartz veins in the Porcupine area are true fissure veins, and that the ore deposits in the said area are actually one of the many links of the great "Appalachian chain."

In conclusion, it may be said that there has been discovered a gold camp in Ontario Province that bears all the necessary indications of becoming one in the true sense of the word, and also one that is within easy access of the commercial centers of the North American continent.

Note.—The various quantitative data in addition to certain geological facts mentioned in this article have been obtained from the government reports of 1909.

METALLIC STRONTIUM

This metal was obtained by fusing pure strontium chloride in a hemispherical iron cathode vessel 25 centimeters in diameter, with walls .6 centimeter thick, with a carbon anode 8 centimeters by 8 centimeters. This allowed a low anode current density and avoided overheating. With a current of 125 amperes and 40 volts for 7 hours, 76 grams of metal were removed in small lumps up to 3 grams in weight. The metal is removed from the mixture by crushing on an iron plate and then sifting away the chloride. Analysis showed it to contain about 98 per cent. of metallic strontium, which is a light metal, with a silvery lustre when cut, gradually becoming yellow and finally white and non-lustrous. It is softer than calcium and can be cut with a knife. It alloys with iron. Hydrogen and nitrogen unite with the heated metal. The specific gravity is 2.55 and the specific heat .0742, corresponding to an atomic heat of 6.5. The iron alloy is rather hard, and decomposes water. This alloy contained 23 per cent. of strontium. *Journal of American Chemical Society.*

EXAMINATION OF STEELS BY CORROSION

A method is described for the examination of manufactured steel (forgings, etc.) in which the polished metal surface is treated either with a 4-per-cent. solution of picric acid in absolute alcohol, or, as a less active reagent, with an iodine solution of 10 parts of iodine and 20 of potassium iodide, in 100 of water. By the action of the solvent, the lines of flow induced in the metal by the mechanical treatment become visible to the naked eye; and thus it is possible to discover the method used for the manufacture of the piece under examination. The effects due to mechanical treatment are generally easily distinguished from initial defects in the metal and from changes induced by heating; in doubtful cases the microscope can be used. M. F. Cloup. (Rev. de Metall., vii, 605.)

ELECTRIC FURNACE FOR ZINC SMELTING

*By Francis A. J. FitzGerald**

A Description of the Furnace. Experiments Showing Temperatures and Efficiency

There is no branch of metallurgy which is apparently more suited to electric furnace treatment than that of zinc smelting. The regular method of zinc smelting is extraordinary in its crudity, inefficiency, and expense, hence the relatively high cost of heat generated electrically is not by any means so serious a consideration as in certain other metallurgical processes. Moreover, the electric furnace possesses certain characteristics which make it specially applicable to the conditions of zinc smelting. In the following paper it is proposed to describe briefly a new form of electric furnace originally designed for zinc smelting, although it has useful applications in other kinds of work.

It is not intended to discuss here the metallurgy of zinc smelting, but to appreciate properly the electric furnace which

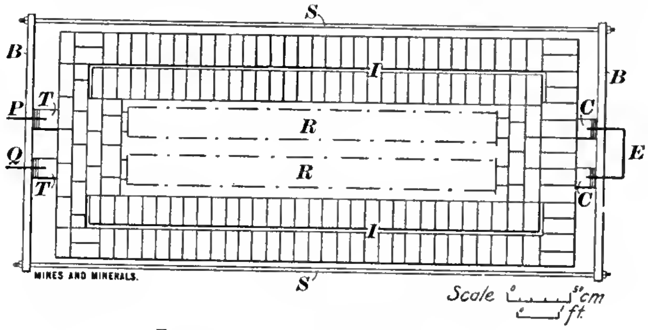


Fig. 1. Plan of Electric Furnace

will be described it will be necessary first briefly to consider the particular method of zinc production for which the furnace was designed. It has long been known that when zinc sulphide and metallic iron are strongly heated the following reaction takes place:

$$ZnS + Fe = Zn + FeS$$

but the reaction does not seem to be complete unless there is a relatively large excess of iron, or unless the temperature of the reaction is very high. Imbert, however, discovered† that by using suitable dissolvents this objection to the process is overcome. Imbert, for example, found that ferric oxide and iron sulphide mixed together in the proportion of one part and three parts, respectively, formed a very fluid bath at a temperature between 1,000° C. and 1,100° C., and that this bath would dissolve six parts of blende. Now when the blende is dissolved in a bath in this way the reaction with iron mentioned above takes place with the greatest ease, is complete, works at a comparatively low temperature, and as a residue produces two distinct substances—a slag consisting of the gangue from the ore, and a ferrous matte which may be used for the regeneration of iron, etc.

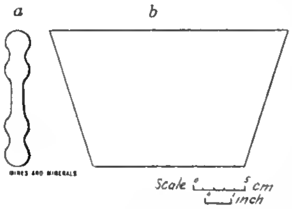

Fig. 2

A great many experiments were made with this process and the results were highly satisfactory, except that it was very difficult to construct a suitable furnace for the purpose. Obviously, working the process in the ordinary zinc-retort furnace would not be satisfactory, for the process should be carried out with a much larger unit than a zinc retort. When it comes to applying fuel heat to such a process numerous difficulties arise which are sufficiently plain without mentioning

* Consulting Chemical Engineer, Niagara Falls, N. Y. Presented before the Congress of Technology at the Fiftieth Anniversary of the Granting of the Charter of the Massachusetts Institute of Technology.
† U. S. Patent 875,579, December 31, 1907.

them in detail This naturally led to the idea of using an electric furnace, and many experiments with various kinds were made. Finally, John Thomson and the author designed a furnace which was used on a large scale in the working of the Imbert process. One of these furnaces of 150-kilowatt capacity was constructed and worked under the author's supervision in Hohenlohehutte, Upper Silesia, with highly satisfactory results.

In order to design a satisfactory furnace it was necessary to keep certain points in view: The furnace must be gas tight; the temperature must admit of careful regulation; the construction must be rugged so as to stand severe usage; the heat losses must be reduced to a minimum, since electrically generated heat is always expensive.

In Fig. 1, is shown plan of the furnace with the cover removed. The walls of the furnace are double, with air spaces *I* which are designed to prevent the loss of heat by conduction through the walls. The furnace is provided with carbons *T*, *T*, *C*, and *C*. The two former serving as terminals which are connected to the source of current by means of cable indicated by *P* and *Q*, while the two latter are simply connector terminals which form the other terminals of the two sections of the resistor *R*, *R*, and are connected by *E*. Bearing on the terminals *T*, *T* and the connector terminals *C*, *C*, are channels *B*, *B*, which are connected with each other by the tension rods *S*, *S*. The channels are, of course, insulated from the terminals. The furnace is lined with a suitable refractory and is provided with a tap hole. The resistor of the furnace is built

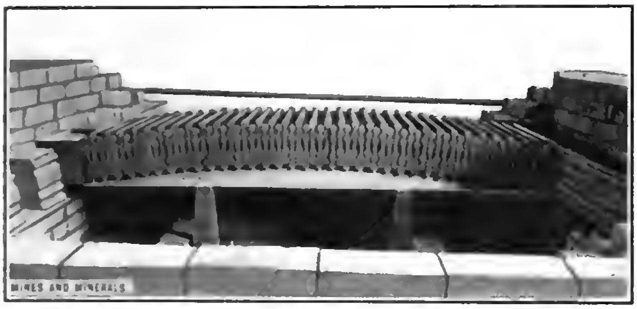

FIG. 3. END VIEW OF RESISTOR

up of a series of corrugated plates, as shown in Fig. 2; an end view of the plate is shown at *a*, while at *b* is shown the shape in which the plates are cut as viewed from the front. In Fig. 3 is shown a view of the plates set up so as to form a resistor. Considering one of the plates it is to be noted that the thickness is not the same from top to bottom, but increases from the bottom up, so that when put in place they form an arch of very long radius, as shown in Fig. 3. Because of the interlocking of the plates this arch form is not necessary, but seems to be desirable in the preliminary assemblage and is also utilized to produce a somewhat greater current density along the lower surface of the resistor. The cover of the furnace, which is not shown in the illustration, carries feeding tubes by means of which the ore mixture may be fed into the bath below the resistor.

The peculiar construction of the resistor plates has two purposes: to give a sufficiently high resistance to the resistor, and at the same time to form an interlocking device so that even if no arch form is given to the resistor yet it will not fall down. A furnace was built with plates having these dimensions: Length at top, 405 millimeters (16 inches); length at bottom, 255 millimeters (10 inches); width, 165 millimeters (6.5 inches). The two sections of the resistor contained 71 plates each. This, when cold, had a resistance of .200 ohm, and when running at the full capacity of 150 kilowatts, and with a temperature in the furnace of 1,400° C., the resistance was .0375 ohm. This resistance is due almost altogether to the contact resistance between the plates, for by calculating the resistance of the carbon itself we find that it would not amount to more than .00064 ohm.

In order to regulate the rate of generation of energy in the resistor there must be some means of varying the voltage at the terminals of the furnace. At Hohonlohehutte, as well as in the FitzGerald and Bennie Laboratories, where these furnaces have been worked, this is done by means of a transformer with several taps brought out from the primary coils which allow the voltage on the secondary circuit to be varied from 50 to 100 volts in 2.5-volt steps, and from 100 to 200 volts in 5-volt steps.

It will be seen that the weakest part in this furnace is the carbon resistor, due to the fact that if working in an oxidizing atmosphere the resistor will be destroyed. In the particular work for which it was designed, however, there would be no danger of this because the furnace is filled with vapor of metallic zinc. During the process of heating the furnace, or at any time when zinc vapors were not generated, there would be danger of burning through air leaking in; but this is easily overcome by keeping a reducing atmosphere in the furnace slightly above external pressure. It has been found by actual experiment that a furnace of this type running continuously for 2 months showed no appreciable wear of the resistor.

The regulation of temperature in this furnace is most satisfactory. In the Hohonlohehutte experiments thermocouples of pyrometers were placed in several parts of the furnace to study the temperature conditions carefully. It was found that the most accurate regulation of the temperature in the furnace was possible, the workman in charge adjusting the rate of generation of energy in the resistor so as to keep the needle of the pyrometer stationary.

The furnace is a highly efficient one. In one of the earlier models, where the heat insulation was far from being satisfactory, careful determinations of all heat losses were made. When working at temperatures between 1,250° C. and 1,260° C. the total heat losses were 33 kilowatts, and when working at temperatures between 1,400° C. and 1,450° C. the heat losses were 42 kilowatts. Consequently, when the furnace is working at full capacity—150 kilowatts—the thermal efficiency at 1,250° C. is 78 per cent., and at 1,425° C. is 72 per cent. No exact determinations of the efficiency of later models have been made, but it is known to be much higher than those given above.

The metallurgical end of the problem has not been completely worked out, but the satisfactory working of the furnace has been clearly demonstrated, and furnaces built on similar principles have been used experimentally with great success in the melting of aluminum, copper, brass, etc. This is thought to be of some interest, as a development in the use of electric furnaces using the heat generated by the passage of an electric current through a resistor. There is a tendency in electric furnace work to employ the arc, which is often a mistake, because of the difficulty in regulating the temperature. Finally, the furnace described above from its construction lends itself readily to adaptations which permit of using the combined heat effects of fuel and electricity, and it is thought that a great future is in store for furnaces of that type.

SODIUM CARBONATE AS AN OXIDIZER

When finely divided, silicon, tungsten, molybdenum, titanium, or such alloys as ferrotitanium, ferrosilicon, phosphor-iron, etc., are strongly heated with sodium carbonate, the metal becomes oxidized, and carbon monoxide is evolved. This is found to offer a convenient method of attacking many metals and alloys which are dissolved only with difficulty by acids. The addition of magnesium oxide to the sodium carbonate renders it more effective, especially for chromium and its alloy, and prevents fusion of the mass. The carbon monoxide is allowed to burn as evolved, in order to avoid the possibility of reverse action. E. Deiss. (Cehm. Zeit., xxxiv, 781.)

COBALT ORE BUYING BY SMELTERS

Written for Mines and Minerals

The Montreal Reduction and Smelting Co., at North Bay, Ontario, propose to eliminate the arsenic to 12 per cent., and smelt the roasted ore in a shaft furnace to silver bullion, speiss, and slag. The speiss is to be crushed, and roasted, and leached with sodium thiosulphate to remove the arsenic. Cobalt oxide, which at one time was almost entirely a product of Europe, is now produced in such quantities as a by-product in smelting Cobalt silver ores, that the restricted market is demoralized and the price of the refined product has fallen from $2.50 per pound in 1908 to 80 cents per pound in 1910. Smelters are not inclined to pay for the cobalt and nickel, and penalize the shipper for arsenic in excess of 5 per cent., and reserve the right to return ore at shipper's expense where nickel is in excess of cobalt. The charges for smelting are graded according to the value of the silver in the ore. The ores of the Cobalt district are smelted in Canada by the Canadian Copper Co., Copper Cliff, Ontario; Deloro Mining and Reduction Co., Deloro, Ontario; Coniagas Reduction Co., at Thorold, near St. Catherines, Ontario; Consolidated Smelting and Refining Co., Trail, British Columbia. Some high-grade ore is shipped to Beer, Sondheimer & Co., Hamburg, Germany; Quirk, Barton & Co., London, England; and Pennsylvania Smelting Co., Carnegie, Pa. Buyers of low-grade ores are, United States Metals Refining Co., Chrome, N. J.; and Balbach Smelting and Refining Co., Newark, N. J.

Bases on which the Different Smelting Companies Fix Prices for Ores of Various Content

The schedules on which payment is made for smelting vary with the kind of ore and the basis of payment adopted by each smelter. Taking as an example the Balbach Smelting and Refining Co.: They pay for the ore 30 days after agreement of assays, and at the silver quotation in New York City, on the date of payment. Their schedule is as follows: Provided ore contains over 1,000 ounces and not over 1,500 ounces of silver, per ton, the smelting charge is $4 per ton of ore, and 93½ per cent. of the assay value in silver is paid for, with 45 cents penalty for each per cent. of arsenic in excess of 6 per cent., and 6 cents for each per cent. of insoluble in excess of iron.

Should ores contain from 1,500 ounces to 2,000 ounces of silver per ton, the smelting charge is $20 per ton, with the same deductions for arsenic and insoluble in excess of iron for fluxing the insoluble matter.

Ores which contain more than 2,000 ounces per ton have 93½ per cent. of the silver paid for and the smelting charge is $19 per ton. The same deductions for arsenic and insoluble in excess of iron are made as in the lower-grade ores. Unless the tariff has changed, the freight to Newark, N. J., is about $9.20 per ton on a 3,000-ounce silver ore, containing 40 per cent. arsenic, 8 per cent. cobalt, and 6 per cent. nickel. The returns to the shipper for such ore would be calculated as follows:

Credits		
3,000 ounces silver at 50 cents per ounce....		$1,500.00
Debits:		
Smelter charges..........................	$19.00	
Smelter deductions, 6½ per cent............	97.50	
Arsenic deductions, 34 per cent.×.45........	15.30	
Freight..................................	9.20	
Assaying and sampling.....................	1.50	142.50
Net return..............................		$1,357.50

The Coniagas Reduction Co. purchases Cobalt silver ores containing but 20 ounces of silver. It would not, however, pay to ship such ore to them, as their charges are much in excess of the value of the ore. When ores contain less than 100 ounces of silver per ton the treatment charge is $10 for 2,000 pounds, unless the ore contains 12 per cent. or over of nickel and cobalt. Their schedule is as follows: Will pay for

	Ounces
75 per cent. of silver contents assaying over...............	20
84 per cent. of silver contents assaying over...............	200
86 per cent. of silver contents assaying over...............	300
89 per cent. of silver contents assaying over...............	500
91 per cent. of silver contents assaying over...............	750
93 per cent. of silver contents assaying over...............	1,000
93½ per cent. of silver contents assaying over..............	1,500
94½ per cent. of silver contents assaying over..............	2,000
95 per cent. of silver contents assaying over...............	3,000

Ore must be delivered in car-load lots Thorold Smelter via Grand Trunk Railway, and is subject to the shipper's risk until sampling is undertaken.

This company pays for cobalt in the ore as follows: When cobalt assays 6 to 8 per cent., 8 cents per pound; when cobalt assays 8 to 10 per cent., 10 cents per pound; when cobalt assays 10+ per cent. 12 cents per pound. When the ore assays less than 6 per cent. nothing is allowed for cobalt.

Beer, Sondheimer & Co. buy high-grade silver ores delivered in New York City, on the following basis dry weight. There is no refining charge. The smelting charge is $30 per ton; a deduction of 6 per cent. being made from the assay value of silver in the ore. Owing to draying, sampling, insurance, etc., this charge is about the same as the United States and Canadian smelters.

The Canadian Copper Co. makes all purchases of Cobalt ore through the Orford Copper Co., of New York City. Their schedule is as follows: The purchaser to make payment for

	Ounces and Over
75 per cent. of silver when same assays...................	100
84 per cent. of silver when same assays...................	200
86 per cent. of silver when same assays...................	300
87 per cent. of silver when same assays...................	400
89 per cent. of silver when same assays...................	500
90 per cent. of silver when same assays...................	600
92 per cent. of silver when same assays...................	800
93 per cent. of silver when same assays...................	1,000
93¼ per cent. of silver when same assays..................	1,300
93½ per cent. of silver when same assays..................	1,600
94½ per cent. of silver when same assays..................	2,000
94¾ per cent. of silver when same assays..................	3,000

Purchaser to make payment of $10 per ton when same contains 6 per cent. cobalt and over; $20 per ton when same contains 8 per cent. cobalt and over; $30 per ton when same contains 12 per cent. cobalt and over.

No payment will be made for cobalt in ores containing less than 6 per cent. cobalt, nor in which the nickel contents are higher than the cobalt contents. Further, the purchaser reserves the right to return at the shipper's expense ore whose nickel content is higher than cobalt content. Ore is to be delivered by the seller f. o. b. cars Copper Cliff, Ontario.

This company, and in fact all smelting companies, assumes no responsibility for ore until it has been taken into its sampler. This company samples free, if the seller's representative is present. Assays are to be made by Ledoux & Co., of New York City, at miner's expense.

Payments are made for 70 per cent. of the silver returnable to the seller, as per the scale, to be made at the New York official price for silver on the first settlement date, which shall be 35 days after the date of which sampling of the ore is completed, and the remaining 30 per cent. on the second settlement date at the New York official price of silver on that date, which shall be 90 days after sampling of the ore is completed. The company reserves the right to deliver upon either or both of the settlement dates above specified in lieu of cash, at its option, such silver bullion (commercial bar silver) as is due the seller in settlement upon these dates, such delivery to be made in New York City.

Settlement for cobalt is to be made 35 days after the completion of the sampling.

The company has put the 75 per cent. silver returnable on ore between 100 and 200 ounces of silver per ton as a penalty clause to apply where ores under 200 ounces per ton were shipped by mistake, and the company does not agree to accept

regular shipments of ore carrying less than 200 ounces of silver per ton of 2,000 pounds.

The Deloro Mining and Reduction Co. receives ore in carload lots f. o. b. Marmora Station, Canadian Northern Ontario Railway. Their tariff is subject to change without notice. Ledoux & Co.'s assays are accepted with the usual provisions as to umpire assays in case the assays of Ledoux and the company's assayer do not approximately agree. No payment is made for cobalt when the ores contain more nickel than cobalt, and no payment will be made for cobalt unless the ore contains 6 per cent. and more; then 10 cents per pound is paid.

This company charges $20 per ton for smelting; pays for 98 per cent. of the silver in ore; and makes a charge of 1 cent per ounce of silver in the ore for refining. Payments made at New York quotations, 75 per cent. in 30 days, and 25 per cent. of the net proceeds in 90 days from the time of sampling.

The Pennsylvania Smelting Co., of Pittsburg, Pa., with works at Carnegie, Pa., purchases cobalt ores ranging from 50 ounces per ton up. They pay for 95 per cent. of the silver less 1 cent per ounce refining charge. There is no payment made for cobalt or nickel, and sometimes arsenic is penalized. The treatment charges are $8 per ton; settling is done in about 20 days after the arrival of the ore at Carnegie.

The richest cobalt ore that the United States Smelting Co. purchases contains 400 ounces of silver to the ton. They do not care for richer ore than this at Chrome, N. J.

ORE MINE NOTES

Lead Production.—The production of refined lead in the United States in 1910 amounted to 470,380 tons of 2,000 pounds. This is an increase of 22,268 tons over 1909. In quantity of lead ore Missouri, as usual, came first with 161,659 tons; Idaho second, with 99,924 tons; Utah third, with 57,081 tons; and Colorado next with 35,685 tons. No other states showed production that reached five figures. The refined-lead product cannot be apportioned according to source of ore, owing to the fact that lead refiners treat smelted products whose origin may, as in custom refining, be unknown to them, the identity of the ore, and thus its original source, being preserved only as far as the smelter. Accordingly, the following table, showing source of lead smelted or refined in the United States, is based on smelter figures. It includes "pig lead" reported by all smelters using Mississippi Valley soft lead ores and "lead" produced at all other lead smelters in this country. The greater part of the product reported by smelters operated in conjunction with refineries is in terms of refined lead. A like part of the antimonial lead product is thus eliminated from the "lead" produced and appears only in the figures of production of antimonial lead. No lead ore from the United States was treated elsewhere during the period covered by the table. Source of primary lead smelted or refined in the United States in 1910 is furnished in tons by the United States Geological Survey as follows:

Total from domestic ores	372,227
Foreign ore:	
Africa	3,499
Canada	44
Central America	7
England	28
Mexico	70,159
South America	3,168
Other foreign	
Foreign base bullion:	
Canada	
Mexico	31,648
Total from foreign ore and base bullion	108,553
Grand total, derived from all sources	480,780

Rhodesian Chrome Ore Shipments.—In answer to inquiries, Consul G. A. Chamberlain, of Lourenco Marquez, Portuguese East Africa, furnishes the following information concerning the shipments of Rhodesian chrome ore through the port of Beira to the several countries in 1908 and 1909:

Country	1908	1909
	Tons	Tons
United States	4,225	11,470
Netherlands	3,612	5,102
France	3,290	3,717
Italy		1,000
Belgium	490	905
United Kingdom	306	677
Total	11,923	22,871

It will be seen that over one-half the quantity shipped in 1909 went to the United States—all to Baltimore.

Santa Rosa Exploration Company.—Volney D. Williamson, a mine owner of Spokane, Wash., who has just returned from the West Indies, announced on April 12 that the Exploration Co., of London, England, through which the Rothschilds conduct their mining operations, has taken over the properties of the Santa Rose de Mazapil Mining Co., and the Santa Rosa Development Co., situated in the state of Zacatecas, Mex. A corporation, known as the Santa Rosa Exploration Co., which is capitalized at $750,000, has been organized to acquire and develop the holdings.

Canada's Asbestos Industry.—Canada produces 82 per cent. of the world's supply of asbestos. The companies operating asbestos quarries and factories in the Dominion are capitalized at $24,290,000. In 1880 only 380 tons of asbestos were produced, valued at $24,700; whereas in 1909, the production amounted to 63,300 tons, valued at $2,300,000. In 1909, 3,000 men were employed in the asbestos industry, and received wages amounting to $1,350,000. Fritz Cirkel, M. E., says in his monograph on chrysotile: "It will not be long before the asbestos slate or shingle business, which is just commencing to be felt, will push its way more and more to the front. Indeed, it is not too much to say that the time is not far distant when fully 75 per cent. of all asbestos produced in the world will be used in the manufacture of asbestos slate and shingles. The asbestos slate business is only 4 years old, but during that short space of time the demand for this article has increased to such an extent that factories for this purpose are being established all over the world."

Treatment Rates Restored.—The rate war growing out of the competition between the United States Reduction and Refining Co. and the American Smelting and Refining Co. for Cripple Creek ore was of short duration. The former made a cut on high-grade ore that was promptly met by the latter. The new schedule, however, was in force only 2 weeks, and the old rates are now in force. None of the independent companies was involved; in fact, because the ore producers have been entirely satisfied, the independent companies have been able to renew contracts at remunerative rates, although the recently-issued annual report of the United States Reduction and Refining Co. makes the complaint that in spite of offering treatment at rates that are not remunerative it has been unable to get an adequate supply of ore.

Will Cyanide Tailing Dump.—John Q. MacDonald, vice-president of the United States Reduction and Refining Co., reports that the new tailing mill, at Florence, is ready to begin operations. It will have a daily capacity of 500 tons, and is expected to make a profit out of tailing that averages only $1.05 a ton. The estimated amount of tailing in the dump is 600,000 tons. As the ore was roasted when first treated, regrinding will be all that is necessary preliminary to leaching with cyanide solution. Tube mills will be used.

Preparations are being made for an active season by placer miners in the Libby Creek district in western Montana. The Libby Creek Placer Mining Co. is arranging for the installation of a saw mill to cut lumber for flumes and buildings about

20 miles south of Libby, Mont., where it holds a large area of ground. Operations have been started on the Rice placer claim in the Republic district, where there is abundant water this spring.

Tungsten in Summit County.—Tungsten ore of high grade, it is reported, has been discovered on Farncomb Hill, in the Breckenridge district of Summit County. The discovery was made by C. S. Laughlin on the old Key West property, a part of the large Wapiti holdings of which Judge Charles Cavender, of Leadville, is the chief owner. The three dredging companies operating on the river-bed auriferous deposits of Summit County are making regular shipments of placer gold. There is an excellent opportunity for a modern cyanide plant to handle Summit County ore, and when built there is promise of the same success that has followed the development of cyanide treatment for Cripple Creek ore.

The Reed Mine.—The first gold mine in the United States was known as the Reed mine. It is 5 miles south of Concord, in Cabarrus County, N. C. At this mine a gold nugget weighing 960 ounces was found, and afterwards, in 1838, the Cabarrus nugget, weighing 444 ounces. Since the latter date several other good-sized gold nuggets have been obtained.

Production of Gold and Silver in Georgia in 1909

Counties	Gold		Silver	
	Fine Ounces	Value	Fine Ounces	Value

Tin Mined in Alaska.—The United States Geological Survey reports that in 1909 about 34,000 pounds of stream tin was mined in Alaska and shipped to England.

Hunter Mine, Idaho.—One hundred thousand dollars is being expended to make the Hunter mine, near Mullan, one of the best equipped plants in the Coeur d'Alene district. Among the improvements contemplated are the enlarging of the mine and the installation of an electric hoist and motor cars for hauling ore from the shaft to the bins on the tunnel level. The capacity of the mill also will be increased from 400 to 800 tons daily. The latter work is to be completed early in June. The electric hoist, upon which work is progressing, will have a lifting power equal to 5 tons. One hundred and fifty men are at work, the principal operations being on the 400-foot level.

Jack Waite Mine, Idaho.—At 1,200 feet, in the lower tunnel of the Jack Waite mine, in the Coeur d'Alenes, Idaho, a 12-foot ledge, half of which is clean shipping ore, has been exposed. More than 1,600 sacks of ore is on the dump. Assays from recent workings show these values: Lead, 78.5 per cent.; $70.65; silver, 5.5 ounces, $2.72; gold, .36 ounce, $7.20. Development work is progressing. The full face of the tunnel is in ore. The next development work will be a raise to the surface for stoping out the ore. This raise will be 550 feet, and the owners believe there is ore all the way.

Iron Ore in Idaho.—According to George Huston, of Mullan, Idaho, there is an excellent opportunity for the owners of the Bunker Hill and Sullivan, and the Morning and Gold Hunter mines to go into the manufacture of iron. Three milling plants in the Coeur d'Alene district discharge into the river 1,000 tons daily of siderite in their tailing. Here is a waste of natural resources that should stir the conservationists. The siderite can be depended on for years, he states, at 1,000 tons daily, because it occurs as a gangue with galena in the large mines of the district.

Accident Compensation in the Transvaal.—During the year ending June, 1910, there were 915 deaths due to accidents in the Transvaal mines of South Africa. This is at the rate of 5.72 per 1,000 employes in the mines, but even then the total number is 139 less than in the previous year. The average compensation paid for white miners' deaths is £528; for native deaths, £10; and for Chinese, £5. To compensate the schedule the Chinese are not getting killed as numerously as the others.

California Mineral Production.—In 5 years the annual production of petroleum in California has grown from $9,007,820 to $32,398,187. Gold has advanced from $19,197,043 to $20,237,570. Macadam production in 1909 reached $1,636,625. Copper amounted in value to $8,478,142, as against $2,650,605 in 1905. The summary of totals for all products for 5 years makes up a great exhibit as follows: 1905, $43,069,227; 1906, $46,776,085; 1907, $55,697,949; 1908, $66,363,190; 1909, $82,972,209. The advance in 5 years, from 1905 to 1909 was $39,909,209, or practically $8,000,000 a year improvement. This growth is now at a much greater rate than the average figures would indicate, being an advance of more than $16,000,000 a year, comparing 1908 with 1909.

Tennessee Marbles.—Tennessee produces a variety of marbles. Black marble streaked with white calcite; mosaic marble; red variegated marble; a fawn-colored marble; variegated by green, red, or white clouds over brownish red marble; dove-colored, pink, yellow, and onyx marbles. About 80 per cent. of the product is for interior decoration.

The Providencia Mining and Milling Co., of Guanajuato, Mex., whose principal property is the Tajo de Dolores, have completed their new stamp mill and cyanide plant and are expecting to start very shortly. The manager of this property is Mr. Wm. H. McCord. The mine has for many years been operated by use of electrical power, which is supplied by the Guanajuato Power and Electric Co., and the new mill and cyanide plant will also be entirely driven by electric motors. The mill comprises a battery of 60 stamps.

When all the machinery in The Veta, Colo., Mining and Smelting Co. is installed at the Parral, Chihuahua, Mex., plant, it will be one of the most modern. The mine and mill are run by electric power generated by the company. Over 40 motors are used in connection with the milling and cyanide work, totaling about 1,000-horsepower capacity. The hoisting and pumping is also done by electricity, making in all about 50 motors, totaling between 1,500 and 2,000 horsepower.

Platinum at High Price.—Platinum, which now is more costly than gold, has been advancing in price in the last few weeks. It is quoted in New York City at $43 an ounce for the hard and $41 an ounce for the soft metal. These are the highest prices ever reached and indicate an advance of about $10 an ounce in the last 6 months. The present upward movement was nearly equaled several years ago. In 1905 pure platinum was selling at $18.50 per ounce. In 1906 the prices steadily advanced until pure platinum sold at $38 an ounce, and hard platinum at $40. Then a decline started and continued until

1908, when the price declined to less than $20 an ounce. The present upward movement started soon afterward. The chief source of supply is the Ural Mountains in Russia, but some is also obtained from South America and Australia.

Tonopah-Belmont Mine Fire.—Some time ago a fire occurred in the Belmont mine, at Tonopah, Nev. It is said to have started in a pile of lumber in the workings of the mine at a depth of more than 1,100 feet below ground. It is supposed to have been started by some miner leaving a candle on one of the timbers in the mine when he came out from his shift.

When the day shift reported there was considerable smoke coming through the main shaft and the men went down into the mine through another shaft. The greater part of this shift of men were ordered out of the mine as soon as it was discovered that the workings were filled with the smoke, but a small force, presumably of volunteers, remained below to fight the fire. The shift boss, Frank Burke, with four other miners, remained to build a bulkhead, and Burke's body was found about 24 hours later in a frightful condition at the bottom of the 1,166-foot winze. The superintendent and foreman, who endeavored to push their way through the smoke were overcome, and when finally brought back to the surface they were unconscious.

Genuine heroism was shown in fighting this fire and in the rescuing of the miners below the ground. William Murphy descended twice through the smoke and brought back two cage loads of miners. The third time he went down he lost his own life, and his disfigured body was brought up later with several other bodies. Seventeen bodies were recovered from the mine, and it is believed that this represents the extent of the loss of life.

The damage done to the mine amounted to practically nothing. When the fire was first discovered no one at the Belmont mine seemed to have a realization of the danger from smoke and gas arising from fire in the confined space.

SOCIETY MEETINGS

The American Society of Mechanical Engineers hold their next meeting at Pittsburg, Pa., May 30 to June 2, 1911. An elaborate intellectual and social program has been arranged.

The Coal Mining Institute of America will hold their Summer Meeting, June 28 and 29, at Indiana, Pa.

The One Hundredth (100) Meeting of the American Institute of Mining Engineers will be held at Wilkes-Barre, Pa., Tuesday, June 6, and continuing through the week. Headquarters will be at Glen Summit a short distance from Wilkes-Barre on the Blue Ridge Mountains overlooking the Wyoming Valley. To the admirers of scenery this is ideal for a meeting. The Institute was organized at Wilkes-Barre, May, 1871, and has now seventeen of the original members living and active in the affairs of the Institute.

The annual convention of the American Institute of Electrical Engineers, will be held in Chicago on June 26 to 30, inclusive. Among the points of interest to be visited are the Ryerson Physical Laboratory of the University of Chicago, where the atomic theory of electricity has been demonstrated by most interesting experiments; the electric furnaces in the steel mills at South Chicago; the enormous electric plant at the Gary, Ind., steel works, driven by gas engines; the central stations of Chicago, famous for their size and modern design; the hydroelectric development of the Chicago Drainage Canal; "Underground Chicago," with its network of electrically operated freight tunnels; the latest large automatic telephone system; several of the largest manually operated telephone exchanges in the world; street railway and other substations of unusual interest; possibly the largest street railway shops in the world, with electric drive throughout, and many other notable electrical applications.

The sessions will be held in the handsome Louis XVI room in the new Hotel Sherman, which will seat 700 people and can be connected with adjoining apartments to seat 1,500 if desired.

While the list of papers to be presented at the convention is not complete, nevertheless there is a formidable list.

Louis A. Ferguson, 120 Adams Street, Chicago, is chairman of the arrangements for the convention. The Chicago members of the Institute are determined to make this the most entertaining and successful in the history of the society.

THE MENNE-OXYGEN MELTING PROCESS

The equipment included in contracts for the use of the Menne process does not cover the tanks of oxygen and coal gas. These are furnished by Linde Air Products Co. When the tanks are owned by the furnace company the cost of oxygen and coal gas is about 2 cents per cubic foot, much less than when the process was first demonstrated in the United States. Experience has shown that two tanks of oxygen and one of coal gas will open a frozen tap hole, cinder notch, or tuyere, in a few minutes. Two men are necessary to operate the apparatus. (Iron Age, lxxxvi, 8.)

NEW INVENTIONS

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates:

Single copies ....5 cents each
Copies by subclasses...............................3 cents each
Copies by classes...................................2 cents each
An entire set of patents.............................1 cent each

PATENTS PERTAINING TO MINING ISSUED APRIL 4 TO APRIL 25, 1911, INCLUSIVE

No. 990,554. Cutter head for mining machines, John C. Hirst, Reynoldsville, Pa.

No. 990,773. Ore feeder for separating machines, Anders Ponten, Berkeley, Cal.

No. 990,633. Rock pulverizing machine, Alfred Godfrey Campbell, Sherbrooke, Quebec, Can.

No. 990,743. Well-drilling machine, Joseph W. Jennings, Quinton, Okla.

No. 990,205. Coal-mining drill, Richard C. Britton, Buxton, Iowa.

No. 989,819. Ore mill, Jonathan P. Smythe, Longbeach, Cal.

No. 989,868. Ore-roasting furnace, Curt Pfaul, Blasewitz, Dresden, Germany.

No. 989,302. Coke oven, Gustav Schwab, Chicago, Ill.

No. 988,995. Mining sulphur, Herman Frasch, New York, N. Y.

No. 989,184. Well-drilling apparatus, Samuel S. O'Connor, Santa Monica, Cal.

No. 989,257. Rope eye for well drills, Joseph J. Herndon, Sharon, Kans.

No. 988,321. Miner's and the like electric safety lamp, Charles Victor Albert Eley, and Thomas Patrick Brady, Birmingham, England.

No. 988,568. Safety brake for mine cages, Charles Hansen, East Rand, Transvaal.

No. 988,622. Mine door, Newton K. Bowman, North Lawrence, Ohio.

No. 988,948. Means for propping mines, Wilhelm Reinhard, Krefeld-on-the-Rhine, Germany.

No. 988,748. Ore-concentrating table, Enos A. Wall, Salt Lake City, Utah.

No. 988,749. Ore crusher, Enos A. Wall, Salt Lake City, Utah.

No. 988,505. Ore-crushing machine, Harry C. Quick, Los Angeles, Cal.

No. 988,396. Talc ore roaster, George A. Stanton, Chico, Cal.

No. 988,437. Apparatus for treating ores, Isaac A. Braddock, Haddonfield, N. J.

No. 988,458. Apparatus for treating ores, Edwin B. Goodwin, Ward, Colo.

No. 988,737. Process of concentrating ores, Walter Murray Sanders, Marion, Ky.

Mines and Minerals

Vol. XXXI—No. 12. SCRANTON, PA.—JULY, 1911—DENVER, COLO. Price, 25 Cents

WEBB CITY LEAD SMELTERY

Written for Mines and Minerals, by Lucius L. Wittich

Methods Used in Handling and Smelting the Ores and in Refining the Product

The completion of the Webb City Smelting and Mfg. Co.'s lead smeltery at Webb City, Mo., has materially increased the demand for the local output of galena, which, when pure, assays 86.6 per cent. *Pb*, and 13.4 per cent. *S*. The local production, however, averages 80 per cent., which is conspicuously higher than the ore from many other districts of the United States. H. O. Hofman, in the "Metallurgy of Lead," places the percentage of lead in the Granby, Mo., product, which is virtually the same as that produced throughout the entire Missouri-Kansas-Oklahoma district, at 84. This, he says, contains 1.25 ounces of silver to the ton. No effort is made to recover the silver content. According to Hofman, Northern England ranks second in the production of high-grade ores, the lead in that country assaying from 70 to 77 per cent. and carrying 8 ounces of silver to the ton. The lead ores of the Southeast Missouri district average 70 per cent. lead, and Hofman does not credit them with containing any silver. The purity of the Missouri-Kansas-Oklahoma district, or the Joplin district, ores, is due to the absence of contaminating metallic sulphides to any great extent. The most common impurities of the Joplin district lead are iron pyrite and blende.

FIG. 1. WEBB CITY SMELTERY

The total production of galena from the Joplin district is now averaging almost 1,000 tons a week, and of this the new Webb City smeltery is handling 250 tons. The capacity of the plant, which now is 300 tons, is to be increased to 500 tons. George W. Moore, of Webb City, president; R. A. Farnham, of Webb City, vice-president and general manager; and John B. O'Reilly, secretary and treasurer, were careful to arrange for a market for their product before undertaking the erection of a smeltery in competition with the lead trust. Only pig lead is produced and this sells on the East St. Louis pig lead quotations, f. o. b. destination. Cartridge works, shot manufacturers, and other users of pig lead in all parts of the East and in the Middle West appear in the books of the new company as purchasers.

As the crude ore will average 1,600 pounds of lead to the ton, and as the recovery of the plant is said to be 95 per cent., the company secures 1,520 pounds of pig lead from each ton of galena smelted. The price paid for the ore ranges from $53 to $55 a ton; the price received for the pig lead is $64.60, this being for the actual metal derived from the ton of galena. This leaves a margin of about $10 a ton, which the smelters declare is reasonable. It is the desire of the company to make a profit of $1 on every 1,000 pounds of ore handled. In the Joplin district, the ore is really sold on a basis of 1,000 pounds instead of a ton, but to simplify comparisons it will be well to consider the standard of weight a short ton of 2,000 pounds. The purchase of the ore is in the open market, competitive bidding among the various buyers being one of the distinguishing features of the Joplin district.

While the process of reducing crude galena into a merchandisable product, capable of being used in any one of a hundred different ways, is simple in principle, the many little details of the smelting really make the work complicated, and there is much more to the task than the mere heating of the ore until it fuses, the temperature of smelting at the Webb City plant being 1,500° F. in the Scotch hearths, and 2,500° F. in the cupola furnace, where the by-products are smelted. Before the ore finally comes out in the form of marketable pigs several treatments are required, and it also is necessary to utilize the by-products in order that the metal recovery may be as thorough as possible.

The Webb City plant, which was arranged with the view of expediting the production, and which also was constructed along sanitary lines, cost $75,000, and consists of about 12 buildings, occupying a desirable position near railroad tracks on the high prairie north of Webb City, and in the greatest lead-producing area of the district. Fig. 1 shows a view of the plant, looking north, while Fig. 2 shows the plan of the more important buildings, exclusive of the office, which is located to the right of the ore bins.

In the buildings used as the bag room, the trails, and the furnaces, Lamar sandstone, which is less subject to destruction from intense heat, is used. All of the yards are paved with concrete, and through this means the loss of lead ore is minimized. Water used at the smeltery comes from a well 943 feet deep, and is pumped to a tank elevated 30 feet above the ground and having a capacity of 12,000 gallons. In case of fire, complete apparatus is at hand; water mains from the city also extend to the smeltery and these would come into use in case of conflagration.

The mineral building, consisting of 18 ore bins, with a total capacity of 2,750 tons, is 24 feet wide and 72 feet long, and is connected with the jumbo furnace, or Scotch hearth, room by an aerial track along which is propelled the ore bucket having a capacity of 2,000 pounds. Concentrates, ready to be smelted, are dumped directly into the bins after being weighed on the office scales. As the bulk of ore purchased comes from the immediate vicinity, much of it is hauled to the smeltery in wagons; however, a portion of it is received by rail from Joplin, Mo.; Galena, Kan.; Miami, Okla.; Carthage, Mo.; Aurora, Mo.; and other smaller places. Some of the galena mined in the Joplin district occurs in chunks that find a ready market at the best prices. Before this can be smelted, however, it must be crushed,

and for this purpose a small crushing plant has been established at the east end of the mineral building. When filled to its capacity, the mineral building will hold enough ore to keep the smeltery running steadily for almost 3 months.

The aerial track runs the entire length of both the mineral room and the jumbo furnace room, the latter being 28 feet wide and 80 feet long. Passing directly in front of the six jumbo furnaces, as shown in Fig. 3, the ore bucket can be dumped into any one of the six concrete ore receptacles, one of which is in front of each hearth, as shown. At either side of the concrete bin used for the ore are two other bins, one for soft coal, which is used for smelting, and one for pulverized limestone, used as a flux. The ore bucket is equipped with a pair of scales which permits the furnacemen to satisfy themselves on the actual amount of ore they receive. In each shift of 6 hours a furnace crew will smelt approximately 7,000 pounds of the concentrate, which is distributed in seven consignments of 1,000 pounds each. Two men are employed at each hearth or eye, and between shifts the lead is permitted to "freeze" in the hearths.

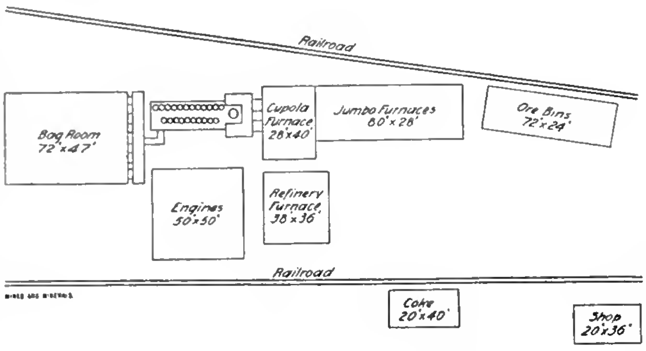

Fig. 2. Plan of Webb City Smeltery

Fig. 3. Jumbo Furnaces

Fig. 4. Refining Department

The furnaces, which are of brick and concrete, with hearthboxes or wells of cast iron, are 5 feet long, 18 inches wide, and the hearthboxes are 7 inches deep. In preparing for the initial charge a wood fire is started in the hearth box and to this is added coal and the blast started. A No. 9 Buffalo blower, driven by a 20-horsepower direct-connected motor, is employed, the air passing into a large pipe or air chamber that runs the length of the furnaces, and from which smaller pipes lead down to the firebox, causing a blast that quickly brings a raging fire. Dampers are so arranged in the smaller pipes that the air blast may be regulated. Ashes and clinkers are removed until the entire hearthbox is a glowing mass of flame. A small quantity of residue from a previous charge is spread over the back part of the fire and the first charge of ore is then given. During one shift approximately 400 pounds of lime flux to 7,000 pounds of ore will be used. As the first charge of ore becomes red hot, the molten lead will begin trickling through the blazing mass and will accumulate in liquid form in the well, the mass slowly lifting the fire until the latter is floating on the bath. When lumps form they are removed and the rich residue is returned to the furnace while the gray slag is thrown to one side to be smelted later in the cupola furnace. About two parts lime are mixed with 30 parts ore and the mixture distributed evenly over the fire and more fuel is added. At intervals the blast is discontinued and then turned on again. A groove from the hearthbox leads across the work stone in front of the box and permits the molten lead to flow into a kettle shown to the right in Fig. 3, from which it is ladled into molds, forming pigs weighing 90 pounds each. The gases from the furnace combustion pass upward through a chimney hood into the fume pipe, as shown, and are drawn by a 100-inch diameter Buffalo exhaust fan operated by a 25-horsepower motor, into the trail, consisting of 11 goosenecks, or 22 stacks, giving a total length of 1,150 feet in which the fumes may cool, before they pass into the bag house. The fume pipe also carries away the gases from the cupola furnace. The goosenecks are shown in Fig. 1 between the bag house on the left and the furnace house on the right.

Fig. 5

The stacks of the goosenecks, which are arranged in two rows, open at the bottom into brick ovens with doors which may be opened at any time and the ashes removed to be resmelted in the cupola furnace. From the end of the gooseneck trail the fumes pass into a last tower connecting with a distributing pipe of greater dimensions than the trail pipe. This runs along the end of the bag room and connects, by five pipes, with as many separate divisions running the length of the bag room. Partitions divide the apartments of the bag room, making it possible to enter any one when the fumes have been shut off and clean out the blue flume which has collected. The operations of the plant need not be impeded by this cleaning-out process.

Each compartment of the bag house consists of a long brick passageway, floored with concrete and ceiled with steel plate, through which the 144 bags of that compartment protrude. These bags are of wool, are 18 inches in diameter, 25 feet high, and are held at the top by steel rods. The

bags are the only inflammable material in the bag house, all the other construction being of steel, concrete, or brick. However, the walls of the structure are of frame. Considering the great distance the fumes must travel before reaching the bag house they are given every opportunity to cool sufficiently to eliminate the probability of conflagration.

Passing into the bag house, the gases, laden with dust, ascend into the hanging bags, where they are filtered, a big portion of the fumes falling into the compartment below. The gases escape through openings in the top of the bag house. Vegetation subjected to contact with these gases is destroyed, and the stifling odor may be detected for half a mile or more from the plant when the wind is in the right direction. As a portion of the fumes adhere to the bags, men with aspirators, dressed as shown in Fig. 5, pass through the building giving each bag a quick shake. The product accumulating in the spaces below is of a fine bluish-gray powder and is known as blue fume. It is possible to utilize this pigment in the manufacture of paint, but it is not put to this use at the Webb City plant. In order that this blue fume may be more easily handled in the cupola furnace it is first converted into porous cakes by burning. The fume is spread in a thin layer over the floor and ignited by burning oil waste. It does not flame, but smoulders for many hours, liberating much heat and some sulphur dioxide. The powder, after being roasted into a porous cake, is free from carbonaceous matter and lead sulphide.

Here the process differs from that employed in the manufacture of white lead at the Picher Lead Co., in Joplin, Mo., where to obtain the white lead powder a second filtration process is employed, the fume from the resmelted blue fume being passed through a second bag house, similar in construction to the first. The product thus derived is a white lead pigment used extensively in paints. As the Webb City Co. does not seek to produce a paint pigment, the blue fume from the cupola mingles with that from the Scotch hearths and passes through the same series of goosenecks.

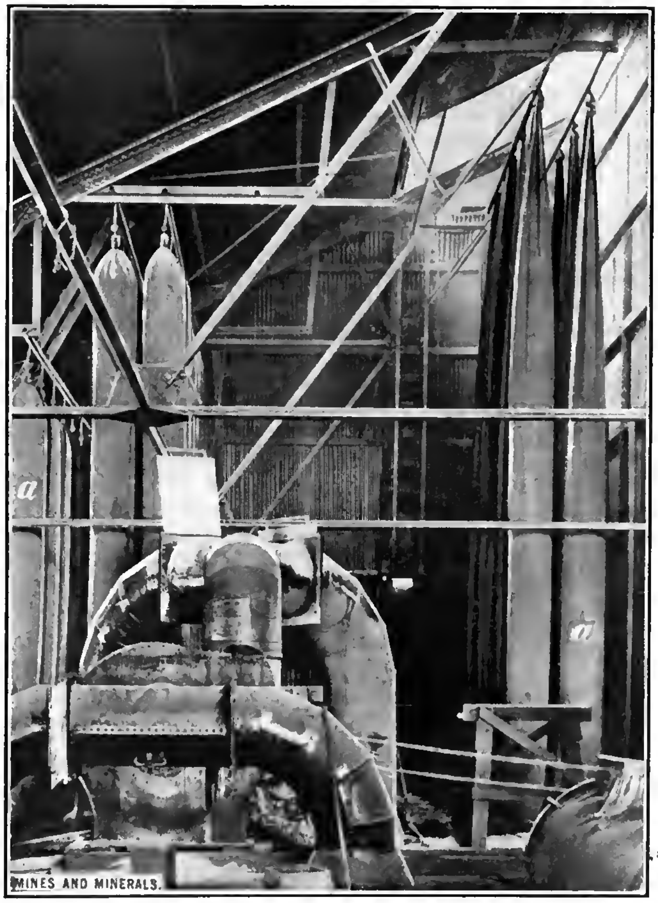

FIG. 6. INTERIOR OF A BAG HOUSE

The cupola is equipped with a Green pressure blower, operated by a 25-horsepower motor. The cupola, which is 16 feet high, smelts the gray slag, which is the original product from the Scotch hearths, and the blue fume, collected both from the bag house and from the brick ovens at the base of the goosenecks. The company estimates the fume to contain 70 per cent. metallic lead; the gray slag to contain 56 per cent. metallic lead; and the ashes or fume from the base of the goosenecks to contain about 56 per cent. metallic lead. From the cupola furnace is secured a black slag, which is the only visible waste of all the material that passes through the smelting process.

In the cupola furnace the heat required to melt the fume and slag is 2,500° F., and the blast fire is kept going continuously. Every conceivable kind of scrap iron, bed springs, rusty rails, tin cans, horseshoes and other junk is used as flux in the cupola. Coke is used as fuel. The company estimates the loss of metallic lead in the black slag at less than seven-tenths of 1 per cent., the other losses being in the waste of ore, smoke, fumes, etc. Of all the metal recovered it is estimated 65 per cent. comes on the first run through the Scotch hearths, and 35 per cent. from the cupola.

Pigs from both the jumbo furnaces and the cupola are remelted in the kettle refinery, Fig. 4, from which the finished marketable product is turned out. This department consists of a huge kettle capable of holding 9,900 pounds of lead. A coal fire is kept burning beneath the kettle and when the metal becomes liquid it is drawn through a tapper valve into the molds shown and in which it cools into 90-pound pigs of lead. Dross skimmed from the kettle goes back to the cupola for remelting, while foam, skimmed from the molds, is returned to the kettle.

As the smelting industry has been looked upon as unhealthful for those employed at the works, the Webb City Co. has constructed its plant with a view of making it as sanitary as possible. The ventilation is excellent and the jumbo furnace room is so arranged that it can be thrown wide open to permit of the free passage of air.

SOLID NITROGLYCERINE

In recent years the E. I. du Pont de Nemours Powder Co. has been manufacturing solidified nitroglycerine to replace liquid nitroglycerine in shooting oil wells. This solidified nitroglycerine is practically the same as blasting gelatin and a considerable quantity of it is used by the oil producers.

The strength of blasting gelatin or solidified nitroglycerine is now generally admitted to be greater than that of nitroglycerine. Manuel Eissler in his book on "Modern High Explosives," page 98, quotes the following from the "Revue d'Artillerie":

"Explosive gelatin is a peculiar description of gun cotton, entirely soluble in nitroglycerine and forming with it a gelatinous or gummy substance more powerful than nitroglycerine, scarcely affected by water, and giving out no trace of nitroglycerine under the strongest pressure."

On page 288 of P. G. Sanford's "Nitro-explosives" it is stated that results obtained by W. Walke, of the United States Artillery, in tests of different high explosives with Quinan's pressure gauge showed the relative strength of nitroglycerine and explosive gelatin as 100 to 106.17.

The du Pont de Nemours Company claim that solidified nitroglycerine is considerably stronger than nitroglycerine. Their blasting gelatin has been used for some time in hard rock tunnels of this country such as the Laramie-Poudre irrigation tunnel in Colorado and on the Roosevelt drainage tunnel at Cripple Creek, Colo.

MINING ON THE GOGEBIC RANGE

*By Percival S. Williams, Ramsay, Mich.**

A Description of the Method of Mining Iron Ore by the Top Slicing System

The method of mining generally practiced on the Gogebic Range is known as top slicing. It differs from the top-slicing system practiced underground on the Mesaba Range in that a pillar of ore about 8 feet in thickness is left over the back lagging on the sublevels during the development stage and during the driving and timbering of the slices in the sublevel pillars, whereas on the Mesaba Range the new slices are timbered up to the floor boards of the sublevels above, leaving no ore to pull back when retreating except that on the sides of the slice, sometimes a slice on each side of the opening slice, and again a slice on one side only.

On finding a new body of ore, drifts and cross-cuts are driven to determine its length and breadth, and 4′ × 7′ raises put up from the drifts at intervals of 25, 50, or 100 feet to prove its height. As raises *a*, Fig. 1, are advanced they are cribbed with 6-inch round timber, opening sets being placed at the sublevel openings *b* so that the work on these sublevels can be started at any time without delay. Poles are laid on top of these opening sets to support the cribbing put in the raise as it is continued above the sublevel. These opening sets consist of two 7-foot posts and a cap on each end of the raise, and are put in the raise 16 to 18 feet apart from floor to floor. This allows for a pillar of ore 7½ to 9½ feet thick from the back of a sublevel to the floor of the next sublevel. Whether or not these sublevels are developed as soon as reached with the raises depends to a large extent on the condition of the ore reserves in the mine. If the ore is needed they are developed at once, but if the management does not need the ore from the section of the mine in which this development work is being done the sublevels would not be developed until a short time before the ore was to be mined. This method of putting up the raises and placing opening sets at the sublevels until the height to which the ore body goes up is reached is by far the most satisfactory, as it permits reaching the top of the ore sooner and makes unnecessary the extensive repair work on the sets of timber that would have been put up in the sublevels if the development work had been done long before slicing on the sublevel began. This feature of additional cost is particularly serious in case the mine is closed temporarily for some unforeseen reason. Frequently, however, ore-reserve conditions are such as to make it advisable to develop the sublevels as rapidly as possible. This is a problem to be worked at each mine, but it is generally conceded that development work on the lower sublevels should be retarded until the time is reached where the ore can be mined to the best advantage.

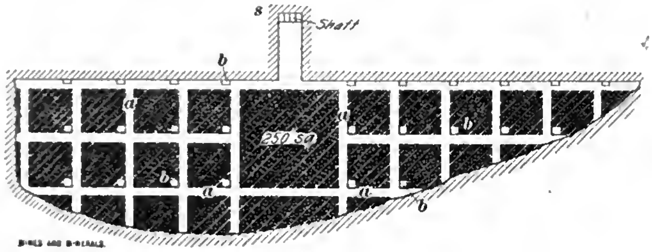

Fig. 1. Plan

It is apparent that the top of the ore body has to be reached and a sublevel driven as near the top as possible before the actual slicing can begin. Sublevels are developed in much the same manner as the main levels, except that the ore is generally blocked out in 50-foot pillars instead of 100-foot pillars as some of the main levels are developed. In one of the mines on the range the main levels are developed with parallel drifts spaced so as to leave 35-foot pillars between them and only occasional cross-cuts are put in. Electric haulage is used on these levels. Raises are put up 25 feet apart. Where the main levels are blocked out in this manner the sublevel pillars are only 25 ft. × 35 ft. The advantage gained by blocking out the ore in this way is in having the raises at more frequent intervals on the sublevels and in producing less curves and crossings on the main level tracks. The cross-cuts on the sublevels are directly over those on the level so as to connect with the raises put up in the ore bodies from the main level cross-cuts. The sublevel drifts are also driven so as to connect with the raises put up from the main level drifts or cross-cuts, and when fully developed the plan of this sublevel would show the ore body cut into blocks about 40 feet square with raises at the corners through which to dump the ore to the main level. A plan of this method is shown in Fig. 2.

* Proceedings Lake Superior Mining Institute, August, 1910.

The sublevel will have a more or less irregular outline on the hanging side, depending upon the manner in which the hanging rock or capping occurs. Small cars of about 1-ton capacity are taken up to the sublevels on which they are to be used. Timber and lagging are usually lowered from a timber raise in the shaft pillar to the sublevels. It is sometimes necessary to hoist the timber and supplies from the main lower level; however, in such cases small "puffers" run by air are installed. From 8- to 16-pound rails are laid in the drifts and cross-cuts on the sublevel floors on which to run the cars, and in some cases only cross-cuts have rails in them, turn sheets being placed at the intersections between the drifts and cross-cuts, and 2″ × 4″ hardwood lumber is used for rails when slicing out the ore.

When the top sublevel is fully developed, the next sublevel below is developed to such an extent that when the slicing is well under way on the top sublevel it may be commenced on the next sublevel below. The ore is sliced out in nearly the same manner at all of the mines, slicing starting at the contact between the rock and the ore on the hanging-wall side and progressing toward the foot-wall side. Two gangs of miners usually work on each pillar, starting on opposite sides and running drifts or cross-cuts parallel and next to their previous openings toward each other until they meet. The openings made by them are timbered with 7-foot timber and the back and side against the ore are lagged. After meeting, the gang starts to retreat in the openings made by them, breaking down the ore over the caps to the floor of the sublevels, where either the miners, or laborers furnished them, shovel it up into cars and tram it to the nearest raise, rarely over 50 or 75 feet away. After reaching the original drift or cross-cut from which the miners started, and having previously covered the floor of the mined-out portion of the sublevel with boards or lagging to enable cleaner extraction of the ore on the sublevel below, they start another slice as before, either leaving about 6 feet of ore

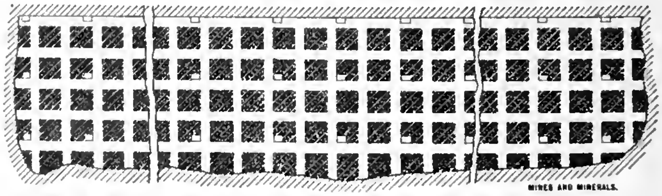

Fig. 2. Plan

between them and the space mined, this ore to be mined when they start to retreat and take the ore over them, or another slice is cut from the side of the ore pillar. Where the latter method is practiced, the ore over the top of the caps in the first slice is usually left to support the material above the ore until the second slice is driven, after which the ore over the space formed by removing the first slice is broken down. The ore over the second slice would be broken down after the third

slice had been driven, etc. When mining in this way, the timber and side lagging put in place with the previous slice is depended upon to hold the top long enough to remove the ore over the slice against the side of which the cave is pressing. In this manner the pillars are gradually pulled back to the safe points of final retreat from the sublevel until the entire sublevel is mined out. In the meantime, however, mining operations are well under way on the lower sublevel, it being the object to mine

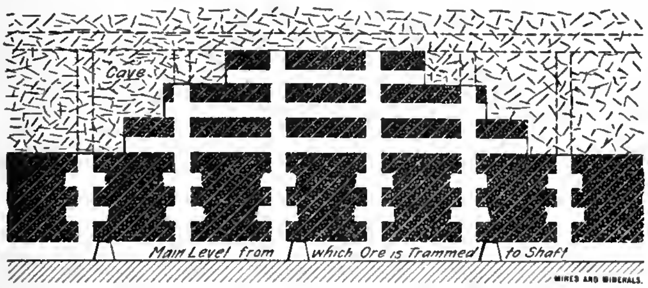

FIG. 3

back the sublevels with the same progress, always having the miners that are working on the next sublevel below working under the cave produced by the men working above them. In this way a longitudinal projection or a cross-section would show the ore in place at any time, forming a succession of steps covered over with gob or waste material, as shown in Figs. 3 and 4.

Any rock encountered in mining out the slices is thrown into the mined-out portion. The timber is usually broken with the blast and also left behind. In this way a gob accumulates, which in the course of time aids materially in holding up the cave while the ore over the slice on the lower sublevel is being mined out. It is advantageous to have the rock capping break down of its own weight on the cave soon after the immediate ore underneath is removed, but at times this capping hangs up for a long period and it is necessary to depend upon the cushioning effect of the accumulation of rock and timber left in the opening during mining operations to prevent a heavy fall of hanging rock from crushing the pillar and timber used to protect the miners. Some ore deposits have extended close enough to the surface to make the surface follow down with the cave, but frequently with smaller ore bodies the surface does not follow readily. This system of mining never exposes a miner to an open stope into which there is danger of his falling, or to being injured by a fall of rock from overhead. Raises occur at frequent intervals into which men might fall from the sublevel. The ore compartment of these raises, however, has six pieces of steel spaced about 10 inches apart, across the opening while the ladder road has a trap door at each sublevel which makes it unusual for a man to be injured by falling down a raise. Accidents will happen, however, so long as there are mines, and the best thing to do is to be on the alert to see that all precautions are taken to prevent them.

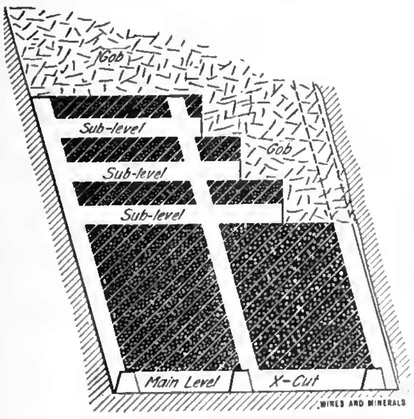

FIG. 4

There is a growing tendency among operators to shorten the distance between raises, in order to reduce the shoveling of ore into cars on the sublevels. The practice of covering the sublevel floors with lumber to help support the cave when mining the sublevel underneath, seems to be growing in favor, even where the gob above is compact enough to enable a good extraction of ore without the use of boards. One thing certain is that by exposing the floor boards, miners on the sublevel below know definitely when to stop work toward a cave above them, and this helps the bosses to keep up the grade of ore by preventing the miners running waste material into it.

While 95 per cent. of the Gogebic Range ore is extracted by means of the top slicing system, certain conditions are met in places which make other mining methods more feasible. Where the ore deposits are narrow, say from 6 to 20 feet wide, developing the ore with sublevels has proved too expensive. Where it is not necessary to make more than one grade of ore, the deposits have been worked by the back stoping method, the underhand stoping method, or a combination of the two. No timber is used in any of these methods. The main level is first drifted on and raises put up about 15 feet apart to the first sublevel which is driven so as to leave 10 feet of ore between the back of the main level and the floor of the sublevel. The raises are widened at the floor of the first sublevel to enable them to accept ore from more territory. Up to this point all three methods are alike. In back stoping, the ore is broken by blasting and drawing enough ore from the chutes to let the miners have room to work. The stope is carried up in this manner within 6 feet of the level above, where if there is waste material resting on the floor of the upper level, the ore is drawn out before proceeding further. In case no waste material is resting on the upper level, the miners go to the upper level and take the 10-foot pillar above the level, and at the same time break the 6-foot pillar under them a little at a time, starting at the point farthest from their means of escape and retreating toward the shaft or limit of the stope. In case waste is being held up by the floor pillar, the waste should have been supported by stulls, otherwise when the pillar finally falls to the chutes below it, the ore will be mixed with waste and some lost in consequence.

FIG. 5

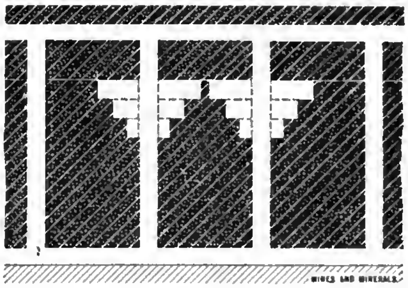

FIG. 6

In the underhand stoping method raises are continued through to the level above, usually 100 feet. Miners start to drift on each side of the raise, leaving about 6 feet of ore between them and the level above. As soon as they are 10 or 15 feet away from the raise other miners start to break the ore that formed the floor for the first gang of miners. These latter miners are in turn followed by others a step lower down, and the stope is gradually worked out, as shown in Fig. 5, the broken ore running into the funnel-shaped raise without much

shoveling in the stope. The hanging wall must be very strong and absolutely self-supporting in order to make this a safe system of mining without the use of timber or stulls. This method is more susceptible to successful ore grading than the back stoping method, but both are much inferior to the top slicing method in this respect. The pillar left under the floor of the upper level is blasted down in the stope from the upper level after the stope is mined out, and serves merely as a protection to the men while working in the stope from anything that might fall from above it, as shown in Fig. 6.

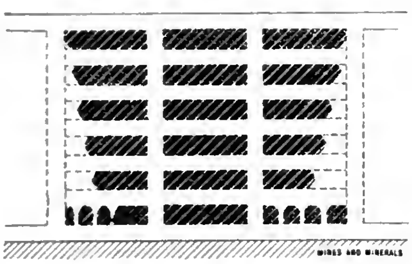

Fig. 7

A combination of these methods has been used after the narrow pillar between the main level has been developed or cut up with sublevels, when it was not known but that the ore might widen out and become softer thereby necessitating the use of the top slicing system. The ore was hard enough to stand without timber in the sublevels, and after its boundary had been established the miners at the sublevels started at the ends farthest from the safe means of retreat and drilled holes which would break half of the pillar above the sublevel and half of the pillar below the sublevel on which they worked, the gang above taking the balance of the pillar above them, and the gang below taking the balance of the pillar under them. The lower sublevels were carried back a little ahead of those above them, in order that the broken ore might have a direct drop to the first level to be trammed out through the chutes, as shown in Fig. 7.

The ore in the Gogebic Range is generally quite soft in structure, making it unnecessary to use drilling machines except occasionally. Holes are bored into the ore with hand augers to a depth of about 5 feet, and 27 per cent. dynamite is generally used to shoot the holes. The foot-wall lies to the north at 60° to 65°, and the hanging rock usually lies in the plane parallel to the foot-wall. The strike is northeast and southwest.

LAKE SUPERIOR IRON ORE NOTES

The Chandler Mine, at Ely, Mich., one of the pioneers of the Vermillion Range, has shipped 9,500,000 tons of iron ore. Two years ago the United States Steel Corporation abandoned the lease, and it was acquired recently by other interests. Explorations have revealed ore comparatively close to the surface; in fact, 30,000 tons have been taken out and stocked during last winter, and it is estimated there are several times that amount in "sight," with prospects of further discoveries.

The Kennedy Mine of the Rogers Brown Co. will be the only Cuyuna shipper this year, for the reason that this range is in its prospecting stage. While there is much to learn about the deposits, enough is known to state that the district will be a factor in Lake Superior ore production. Lean ore high in silica exists in abundance, and the problem consists in finding merchantable ore in quantities. Many of the Lake Superior iron mining concerns, while indirectly interested in the Cuyuna, have adopted the policy of letting others do the pioneer work. However, there is considerable exploration being carried on that is likely to produce several shipping mines in the next two years.

Plumer, Wis.—Prospecting is proceeding in the vicinity of Plumer, Wis., at the western end of the Gogebic Range. It is expected that while the Lake Superior iron ore region as a whole will show decreased shipments in 1911, the Gogebic district will produce as much as last year, namely, 4,315,000 tons.

The Newport Mine of Ferdinand Schlesinger, of Milwaukee, shipped 1,180,000 tons in 1910, which is more than twice its output for any single season with the exception of 1909, when for the first time it attained the million-ton mark. A few years ago this property was considered of so little value that orders had been received to close the mine on the day that a diamond drill, boring from the bottom of the shaft, struck a great deposit of high-grade ore. Since that time as much as 5,000 tons of ore have been taken from that shaft in a single day, this from a depth of 2,000 to 2,400 feet, and this rate can be maintained for some years. It is the Newport that gives its employes each Christmas time an amount equal to their earnings during the month of December.

The Norrie Group.—The steel corporation's Norrie group, on the Gogebic Range, comprises the Norrie, East Norrie, Aurora, Old Pabst, and New Pabst properties, from which a production in excess of 1,250,000 tons is expected this season. The Norrie group has extensive ore bodies—which are still many years from the point of exhaustion—and in addition advantage is being taken of the developments at the Newport. The ore mined in the latter property extends into the steel corporation area and the New Pabst is now being opened on that particular formation. The Norrie group has to its credit a production of 25,000,000 tons.

The Ashland Mine of the Cleveland-Cliffs Iron Co. is counted on this season for an output approximating 225,000 tons. Next to the Newport and the Norrie, it is the largest shipper on the Gogebic Range. The Cleveland-Cliffs Co. have so rejuvenated this mine that it is one of the finest in the Lake Superior region.

The American Mine on the Marquette Range, west of Ishpeming, that was idle from 1893 to 1907 has been acquired by J. R. Thompson and the M. A. Hanna interests. Because the old workings had been robbed, it was necessary to sink deeper in order to reach good productive ground. West of the American, large bodies of ore have been found by diamond drilling and its development is to be started shortly. Part of this land which is controlled by the G. J. Maas interests is owned by the county of Houghton, Mich. Mr. Maas has requested of Houghton County a 50-year instead of a 30-year lease, with the privilege of renewal for a similar period provided that by that time $1,000,000 has been paid in royalties.

Palmer Lake Mine.—A new shipper in the Marquette Range this season will be the Volunteer Ore Co.'s Palmer Lake mine. Thomas F. Cole, of Duluth, formerly in charge of the steel corporation's Lake Superior interests, is interested in the Volunteer company, and while on a recent visit to the property he took occasion to deny any knowledge of the prospective formation of a new steel and iron combine.

The Cleveland-Cliffs Co. is to erect a number of modern mine buildings at its Negaunee property, including a miners' change house, which will be one of the largest and most complete in the Lake Superior district, an office building and a laboratory. With the new structures completed and the new concrete shaft in commission, a considerable portion of the surface will be permitted to cave into the underground workings. The company has started the construction of its dam on the Carp River near Eagle Mills. The dam, it is estimated, will develop 7,500 horsepower.

Lake Superior Southern Railway.—Some little interest has been created in Marquette and Menominee Range circles on account of reiterated reports of an intention to put through the Lake Superior Southern Railway project, the line to extend from Huron Bay, Lake Superior, southerly to Madison, Wis., there connecting with the Illinois Central Railroad tapping en route both the Marquette and Menominee iron districts.

Iron River District.—An interesting development in the Iron River district of the Menominee is the discovery of ore at a depth of 212 feet on the Lindahl property at Beechwood.

SPECIFIC GRAVITY ESTIMATION OF PULP

*By F. B. Hyder**

In order to properly control operations and to be able to make those comparisons between results actual and theoretical, upon which depend success and improvements in cyaniding ores, it is necessary to know the weight of ore treated.

Formulas for Determining the Specific Gravity of Slime Solutions and of Dry Slimes

Where cyanide plants are not arranged so that it is possible to determine by weighing the quantity of ore treated per day or the amount fed into a particular tank, resort is had to the estimation of the contents of the tanks filled, from the specific gravity and volume of the pulp.

For this purpose, the inside measurements of each tank are taken, the volume per foot of depth, and the total volume to one or more convenient levels, marked on the inside of the tanks by painted rings, are calculated and all these data observed and calculated, are recorded on the working drawings of the plant. The volume of the pulp in any tank at any time may then be readily calculated by reference to the drawings of the plant, after measuring from its surface to one of the standard levels.

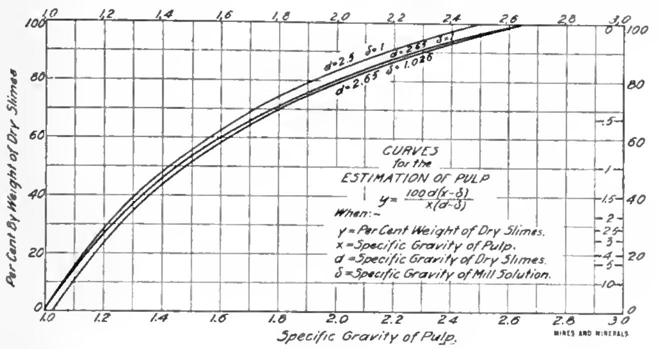

FIG. 1

A liter flask filled to the mark with a sample of the pulp, taken under conditions ensuring, so far as possible, its being representative, is weighed. This sample is best obtained by means of a narrow-necked flask attached to a long pole, so that it may be submerged during the agitation of the contents of the tank. If the pulp is transferred to another vessel before weighing, it should be kept agitated during the process. The weight expressed in kilograms, less the known weight of the flask, is the specific gravity of the pulp.

In the same way, the specific gravity of the mill solution in use may be determined. In practice it has been customary to ignore the fact that the specific gravity of cyanide mill solutions is materially different from that of pure water, and apparently the extent of the error introduced is not generally appreciated. The writer has not been able to find published figures for the range of density of mill solutions. Perhaps some member of the Society can supply them from his experience. Julian and Smart†, however, give as the average density of cyanide solutions (mill solutions) 1.026. From the curves referred to hereafter, it will be seen that the error, assuming this figure to be correct, amounts to from 2 to 3½ per cent. of dry slimes per ton of pulp, in the ordinary range of pulps. The ore tonnages calculated by the usual formulas would therefore be in error from about 4 per cent. for a 1 to 1 pulp, up, increasing rapidly with the dilution of the pulp. The importance of this point is evident.

The average specific gravity of the dry slimes being treated should also be determined. This also is often neglected. It may be done in two ways, which should, taking proper precautions, give identical results.

1. Place a kilogram of the dry slimes representative of the ore being treated in a weighed liter flask and add pure water, mixing thoroughly, until the flask is full to the liter mark. Bring to a boil, adding water if necessary to keep flask filled, then weigh. The weight in kilograms less (1 plus the weight of the flask), is the amount of water added. Call this w. Then:

The specific gravity of dry slimes $=\frac{1}{1-w}$, a simple and more convenient form of the general formula:

$$\text{Specific gravity dry slimes}=\frac{\text{Weight of dry slimes in air}}{\text{Weight of dry slimes in air}+\text{weight of (flask + water)}-\text{weight of (flask + water + slimes)}}$$

2. After determining the specific gravity of a sample of pulp representative of the ore being treated, evaporate a liter of it to dryness. Determine the percentage of dry slimes from their weight. Then:

$$\text{Specific gravity dry slimes}=\frac{\text{Specific gravity of pulp}\times\text{per cent. of dry slimes in pulp}}{\text{Specific gravity of pulp}\times\text{per cent. dry slimes in pulp}-100\text{ (specific gravity of pulp}-1)}$$

W. A. Caldecott* finds that when slimes have been dried, the pulp afterwards formed in the first method must be boiled to expel air or the result obtained will be low.

Having thus briefly indicated the methods of determination of the constants involved, we will proceed to the derivation and use of the formulas.

Then let x = specific gravity of the pulp;
d = specific gravity of the dry slimes;
y = per cent. by weight of dry slimes;
δ = specific gravity of mill solution.

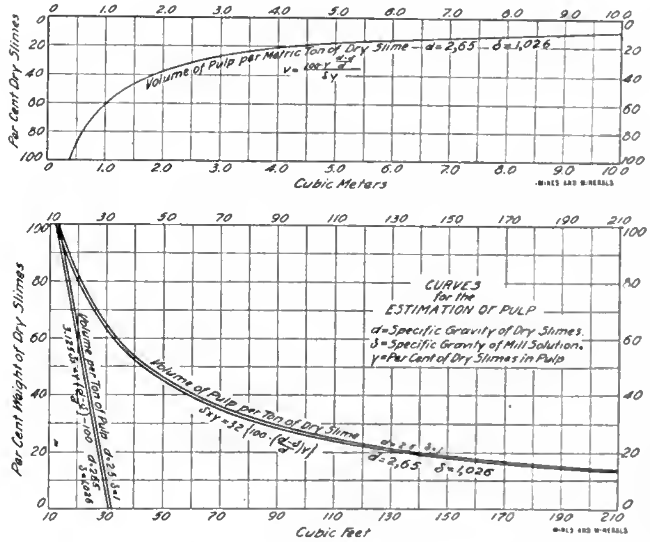

FIG. 2

The formula of the second method of determining the specific gravity of dry slimes may then be expressed:

$$d=\frac{xy}{xy-100(x-1)}$$

Since the volume of unit weight of pulp equals the sum of the corresponding volumes of the dry slimes and of the mill solution, we have:

$$\frac{y}{100\,d}+\frac{100-y}{100\,\delta}=\frac{1}{x}$$

* Colorado Scientific Society, Vol. IX, page 417.
† "Cyaniding Gold and Silver Ores," page 433.

* Reprint Proceedings Chemical and Metallurgical Society of South Africa, pages 373-375.

or
$$y=\frac{100\,d\,(x-\delta)}{x\,(d-\delta)} \qquad (1)$$

and
$$x=\frac{100\,\delta}{100-y\dfrac{d-\delta}{d}} \qquad (2)$$

The percentage by weight of solution in the pulp is then:

$$100-y=\frac{100\,\delta\,(d-x)}{x\,(d-\delta)} \qquad (3)$$

and the ratio of solutions to one of dry slimes is—

$$\frac{\delta\,(d-x)}{d\,(x-\delta)} \qquad (4)$$

The weight per cubic foot of pulp in pounds is the product of the weight of a cubic foot of water by the specific gravity of the pulp:

$$\frac{6250\,\delta}{100-y\dfrac{d-\delta}{d}},\text{ or } 62.5\,x \qquad (5)$$

Or expressed in tons of 2,000 pounds avoirdupois:

$$\frac{3.125\,\delta}{100-y\dfrac{d-\delta}{d}},\text{ or } \frac{x}{32} \qquad (6)$$

The volume of 1 ton of pulp in cubic feet is the reciprocal of (6):

$$\frac{100-y\dfrac{d-\delta}{d}}{3.125\,\delta},\text{ or } \frac{32}{x} \qquad (7)$$

The weight of dry slimes in 1 cubic foot of pulp will be from (1) and (3):

$$\frac{62.5\,d\,(x-\delta)}{d-\delta} \qquad (8)$$

The number of cubic feet of pulp containing 1 ton of dry slime will be from (7):

$$\frac{100-y\dfrac{d-\delta}{d}}{.03125\,\delta\,y}=\frac{32\left(100-y\dfrac{d-\delta}{d}\right)}{\delta\,y} \qquad (9)$$

From (7) and (1) we have for the volume in cubic feet per ton of dry slimes in terms of the specific gravity of the pulp:

$$\frac{32\,(d-\delta)}{d\,(x-\delta)} \qquad (10)$$

For the case where $\delta=1$, the above reduce to some of those given by W. A. Caldecott in the Reprint of the Proceedings of the Chemical and Metallurgical Society of South Africa, page 837, in a table of slime pulp formulas which is of great value.

For $d=2.5$ and $\delta=1$ the above formulas become:

$$y=\frac{1{,}000\,(x-1)}{6\,x} \qquad (1a)$$

$$x=\frac{1{,}000}{1{,}000-6\,y} \qquad (2a)$$

$$\frac{1{,}000\,(2.5-x)}{6\,x} \qquad (3a)$$

$$\frac{2.5-x}{2.5\,(x-1)} \qquad (4a)$$

$$\frac{62{,}500}{1{,}000-6\,y} \qquad (5a)$$

$$\frac{31.25}{1{,}000-6\,y} \qquad (6a)$$

$$\frac{1{,}000-6\,y}{31.25} \qquad (7a)$$

$$104.16\,(x-1) \qquad (8a)$$

$$\frac{3.2\,(1{,}000-6\,y)}{y} \qquad (9a)$$

$$\frac{19.2}{x-1} \qquad (10a)$$

which are formulas in general use but which give only approximate results.

Where metric units are used we have the weight per cubic meter in metric tons is numerically equal to the specific gravity x, and in terms of the per cent. of dry slimes:

$$\frac{100\,\delta}{100-y\dfrac{d-\delta}{d}} \qquad (6b)$$

and this weight may be read off directly from the plot of formulas (1) in Fig. 1 for any desired value of y.

The volume of 1 ton of pulp in cubic meters is the reciprocal of (6b):

$$\frac{100-y\dfrac{d-\delta}{d}}{100\,\delta} \qquad (7b)$$

The volume of pulp containing 1 metric ton of dry slimes is in cubic meters:

$$\frac{100-y\dfrac{d-\delta}{d}}{\delta\,y} \qquad (9b)$$

or, in terms of the specific gravity of the pulp:

$$\frac{1}{x} \qquad (10b)$$

For every-day use it will be found advisable to plot the curves corresponding to these formulas, in which the proper values, determined as indicated above, have been substituted. This may be done on ordinary cross-section paper, as shown in the accompanying diagrams. These curves are preferable to tables calculated from the formulas, such as the excellent ones calculated for $d=2.7$ and $\delta=1$, given by W. A. Caldecott, in the reprint of the Proceedings of the Chemical and Metallurgical Society of South Africa, page 374, both for facility of use and calculation, while the smoothness of the curves is an excellent check on the calculations. In operation and design they will be found useful in a variety of ways.

Fig. 1, showing the curves corresponding to formulas (1) for $d=2.5$, $\delta=1$; $d=2.65$, $\delta=1$; and $d=2.65$, $\delta=1.026$, shows clearly the effect of variation in the value taken for either d or δ. It will be seen that in the range of pulps in practice, the error due to the assumption of the specific gravity of the mill solution to be that of water, may be greater than that introduced by the assumption without determination of the mean specific gravity of the ore. A variation of .15 in d makes a difference equal to that caused by a change of only .026 in δ for a 1 to 1 pulp. For more dilute pulps, the effect of a variation in d rapidly decreases while that due to a variation in δ increases.

It is to be noted that the above formulas apply not only to slime, but to any pulp; i. e., to any mixture of solid particles and a liquid where there is sufficient liquid present to at least fill the voids between the solid particles. At what point this condition no longer obtains is in part dependent on the sizing of the solid particles and is a matter for experiment. Beyond this point the formulas fail. I am not prepared to discuss this further than to say that they hold good for any slime obtained by decantation and therefore will fill the needs of practice.

VANADIUM IN CAST IRON

Vanadium entered into practical metallurgy about 1903, when rich deposits of it were discovered in the Andes of Peru. Vanadium exerts a very powerful influence on steel. One or two-tenths of 1 per cent. raise the elastic limit of mild carbon steel about 50 per cent. or more, without impairing the ductility, and vanadium steels have a very high dynamic strength. Vanadium cleanses the cast iron from oxides and nitrides, eliminates porosity and produces sound castings. In chilled cast iron vanadium produces a deeper, stronger chill, and one less liable to spall or flake. It greatly diminishes the wear on cast iron cylinders. In malleable cast iron the tensile strength is improved about 12 per cent. Geo. L. Norris. (Iron Age, lxxxvi, 5.)

STOPING-DRILL STEELS*

It is essential to the most efficient results in stoping with hammer drills, that everything about the machine itself be kept in the best possible condition. It is just as essential that the drill bits be properly formed, sharpened, and tempered for the work to be done, and that an abundance of sharp steel of the right gauges be constantly available. Poor blacksmithing and the use of wrongly shaped steels or those whose gauge is worn down, will cut down drilling speed, and waste air power and labor to a surprising degree. The following suggestions for the use and care of stoping-drill bits are reprinted from a circular of instructions sent out with the Sullivan stoping drill.

Result of Tests to Determine the Proper Shape and Temper of Bits

The form of drill steel which has been found to be the most practical for use with this machine is the 1-inch heavy ribbed, cruciform solid steel. This type not only by its shape provides greater clearance for the cuttings to fall from the hole being drilled, but also provides greater bearing and wearing surface for the part which enters the bushing than steels of any other shape. The shape of the bit which will give the best results in any particular kind of ground must be determined by experience, for a bit which proves its efficiency under certain conditions may be found inadequate in others, and a very slight change in its shape may bring about surprising results. For the foregoing reason it is impracticable to advance any hard and fast rule to follow in shaping stoping-drill bits, but, as a general rule, the cross bit, sometimes modified to the x-shaped, gives the best results, and such other modifications as the length and thickness of the wings, the angle of the cutting edge, the shape of the end, whether rounding, pointed, or flat, may be determined only by experience in the particular kind of ground in which they are used.

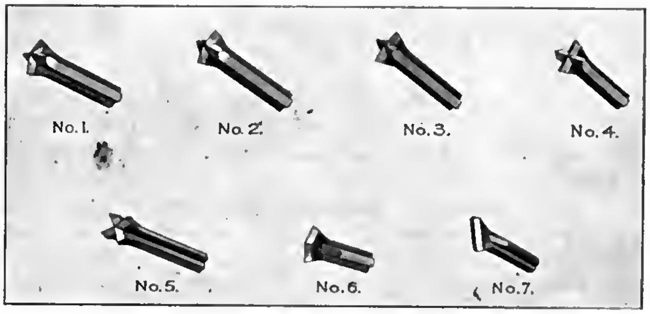
The length of the wings is dependent to a great extent upon the hardness of the ground. If extremely hard, long wings are desirable, as they are capable of withstanding the blow much better than short, flaring ones; while, on the other hand, short wings give the bit more clearance and enable the drill to be rotated easier for a given amount of reduction in the size of the gauge. The accompanying table gives the results obtained by experiments on the seven different styles of bits shown in Figs. 1 to 7, which were operated under the same conditions, so far as consistent, in a moderately hard granite.

Shapes of Hammer Drill Bits and Relative Drilling Speeds

Description of Bit	Duration of Runs Minutes	Diamond Hole Drilled Inches	Average Depth Drilled per Run, 70 lb. Pressure Inches	Average Depth Drilled per Run, 85 lb. Pressure Inches	Remarks
No. 1 25° Diamond point + .	2	1 5/8	6 5/8	8 1/2	Spots easily. Hole rifles slightly. Rotation easy. Gauge does not wear rapidly.
No. 2 25° Diamond point x.	2	1 5/8	6	7 3/4	Spots easily. Drills round hole. Rotation easy. Gauge fairly durable.
No. 3 Convex + ...	2	1 5/8	6 1/8	8 1/4	Spots easily. Hole rifles slightly. Rotation easy. Gauge does not wear rapidly.
No. 4 Flat + ...	2	1 5/8	6	7 1/2	Difficult to spot hole. Hole rifles badly. Rotation hard. Gauge fairly durable.
No. 5 4° Concave + ...	2	1 5/8	5 3/4	8 1/4	Difficult to spot hole. Hole rifles badly. Rotation hard. Gauge fairly durable.
No. 6 25° Pointed Bull – ...	2	1 5/8	5 3/4	7	Spots easily. Drills round hole. Rotation easy. Gauge wears rapidly.
No. 7 Flat Bull –	2	1 5/8	5 13/16	7 1/4	Difficult to spot hole. Hole rifles badly (3 flutes). Rotation hard. Gauge wears rapidly.

Under all conditions the faces or outside edges of the wings should be made flat, with square corners, and never rounding like a figure 8. This is necessary to maintain the gauge of the hole and greatly facilitates the removal of the steels if the hole is drilled at a flat angle.

Before starting, the proper steels needed to complete the hole should be picked out. It should be carefully determined just how much work each drill bit will do before the gauge begins to wear; and the operator should never try to use a bit the second time if the gauge is worn, even if it is sharp on the cutting edge. Furthermore, a drill bit should never be used



Figs. 1 to 7

if the cutting edge is dull, for not only is the drilling speed of the machine reduced, but the cushioning effect which it otherwise gets, due to the penetration into the rock for every blow delivered, is lost, with consequent greater rebound and jar on the moving parts.

A proper gauge for each length of steel should be established and rigidly adhered to, so that the following bit will work freely in the hole. When this system of gauges has been formed, a set of corresponding templates should be made up to insure uniformity in the bits.

Tempering.—The bits should be tempered to suit the particular character of the ground they are used in. The rear or striking end of the drill steel should also be slightly tempered and the face should be kept ground off flat with the edges slightly rounded. A drill steel should not under any circumstances be inserted in a machine if the shank end is rounded or otherwise out of shape, for it will have a tendency to hollow out the striking plug with consequent breakage of this part.

* *Mine and Quarry.*

LAKE SUPERIOR COPPER NOTES

The Mass Consolidated Mining Co., at its annual meeting added two members to its directorate, Francis L. Maguire and Elton W. Walker. It is expected that the rock taken from the mine during the present year will average 17 pounds per ton, which is considerably better than 14.59 pounds, the 1910 average. After another year of development work the mine will be in shape to greatly increase its output. Diamond drill work has started in the Evergreen tract of the Mass company to search for the Algomah vein. The company plans to sell a tract of timberland that is outside of the mineral range. The

Mass Consolidated made a profit from its 1910 operations of $217,798, which compares with a loss of $45,005 in 1909. The company sold 1,321,885 pounds of copper in 1910, for which it received $363,477.

The Tamarack Mining Co.s' annual report shows a loss from mining operations in 1910 of $172,246, or, including interest paid, a net loss of $191,349, compared with $128,546 for 1909, and $235.606 for 1908. The production of copper was 11,063,606 pounds.

The Victoria Copper Mining Co. shows a loss for 1910 of $37,925. Receipts were $152,193 and expenditures $190,118. The company produced 1,164,564 pounds of copper, a slight increase over the previous year. It is evident that shareholders will be called upon for further funds should the management decide to continue operations along the lines now being undertaken.

The operations of the *Atlantic Mining Co.* in 1910 resulted in a loss of $32,162. Receipts totaled $24,671 and expenses $56,834. But little encouragement has attended exploratory work in section 16 of the property, and the future of the company depends principally on what the old portion of the property will reveal.

The Quincy Mining Co. in 1910 made a profit of $725,871, compared with $787,504 in 1909. It produced 34,177,380 pounds of copper last year, against 35,025,225 in 1909. The diamond drill at the Michigan mine, in Ontonagon County, is believed to have passed through the Baltic lode, some copper being taken out in the core. This is of the utmost importance to the Michigan mine, which has about 5,000 acres of mineral lands.

Cost of Milling.—A great deal of interest is caused throughout the copper world by the report that 12 Lake Superior copper-mining companies are joining hands in an endeavor to mill rock at an outside cost of $1 per ton and to produce metal at an outside cost of $1.25 per ton of rock handled. If the proposition can be carried through successfully, rock carrying 10 pounds of copper or more to the ton can be treated at a profit, with copper selling at 12½ cents per pound, and rock carrying 9 pounds of copper to the ton can be milled at a profit with copper selling at 14 cents. A great deal of the rock that is now thrown aside as being of no value could then be treated at a profit.

The Keweenaw County Mines.—At the 1,500-foot level of the Ojibway mine the showing is equal to that of any of the other mines on the famous Kearsarge lode. The rock is full of fine grade stamp copper for the entire width of the lode, which averages 18 feet. Considerable epidote also shows in the rock. In a new opening on the 1,100-foot level the ore is said to be even better than on the 1,500-foot level. News from the Mohawk, which, like the Ojibway, is one of the newer of the Keweenaw County properties, states that the ground tributary to shafts No. 5 and No. 6 has been improving with depth and at No. 6 some of the finest ore found on this property has been exposed.

At the Ahmeek, a Keweenaw property, the openings in No. 3 and No. 4 shafts are more than fulfilling expectations. An abundance of fine stamp rock is being found and developed.

The annual report of the Centennial mine emphasizes the statement that the Kearsarge lode in the Centennial ground is not a paying proposition, with metal selling at present prices.

Because of the state of the metal market local business houses have started a campaign of retrenchment. Many workers have been laid off and others will follow.

During the last six months thousands of people have moved out of the district. More are leaving every week and more will follow. Many are taking land in Minnesota, Washington, Oregon, Florida, and Texas. A large colony was recently organized, almost all copper country miners, in Michigan, to raise fruit.

COPPER CONVERTER FLAMES

*By Donald M. Levy**

There are two main stages in the process of Bessemerizing copper mattes. The first is essentially the elimination of the iron sulphide; the second, the final sulphur elimination.

The Successive Stages in the Bessemerizing of Copper Mattes as Indicated by the Converter Flame

The first stage of the process is known as the "slagging stage," and is characterized by a green flame caused chiefly by the formation of iron-silicate slag. The reactions during this stage are well known; the oxygen of the air which is blown in yields oxides of copper, iron, and sulphur, the former of these immediately reacts with the iron sulphide still remaining and reforms copper sulphide, with the production of more iron oxide. The iron oxide combines with the silica present, chiefly in the lining, and produces a ferrous silicate slag. The corresponding sulphur escapes as SO_2.

The chief product of this first stage is a white metal, practically pure copper sulphide.

When the slagging stage is completed, the slag is poured off and the white metal blown up to blister copper. This constitutes the second main stage of the process.

The chief reaction now is the elimination of the sulphur, and the production of metallic copper—brought about by the action of some copper oxide, first produced, on the copper sulphide present. The flame during this period is smaller, thin, fairly non-luminous, and red-purple to bronze-purple in color.

In addition to these two main color stages, there is a rich red-brown color on first blowing, and a blue-white color at the end of the slagging stage.

The first of these is partly due to the coal thrown in, also to foreign ingredients in the matte which are the first to be oxidized; possibly also to an undue proportion of sulphur burnt out at the lower temperatures which obtain on commencing the blow, and also to unslagged iron oxide.

The blue-white flame, which marks the finish of "slagging," is dealt with later.

The progress of the blowing from copper matte to white metal, and thence to blister copper, is indicated and controlled at the smelter by means of the appearance of the flame issuing from the nose of the converter. The successive changes in their aspect are quite noticeable, and after some practice the stages of the operation can be readily followed. The changes in form and color are gradual, but the skimmer at a glance is able to tell how his converter charges are progressing and to give a shrewd judgment as to the temperature, composition, and nature of his metal and slags.

In general character, the color sequence of the converter flames does not vary much in different localities, but the body and luminosity depend very largely on the nature of the charge and working conditions. The colors are intensified by very hot metal, high blast pressure, and rapid working; also to a great extent by the presence of what might be called secondary constituents in the matte, such as zinc, lead, or arsenic, which, liberating heavy white fumes, increase the luminosity considerably.

There are usually four distinct variations in the appearance of the flame, and these are indicated as follows:

At the commencement of the blow—oxidation of secondary constituents, burning of iron, sulphur, and coal; dark reddish-brown flame, accompanied by much smoke.

Slagging stage—iron sulphide oxidation and formation of iron-silicate slag; vivid apple-green flame.

White metal stage—copper oxidation and formation of copper silicate; white-blue flame.

Blowing to blister copper—sulphur oxidation; thin red-purple flame.

* Institution of Mining and Metallurgy, November, 1910.

The system of working off charges of matte in the converters varies at every plant, and even at the same plant, depending on the rate of production, grade and supply of matte, and its temperature; condition of converter lining, and the state of affairs at the casting and refining furnaces; so that all the cycle of changes may not be seen in regular succession at one converter, which might be kept blowing to white metal with successive additions of fresh matte, or blowing to blister copper with continual additions of white metal from other converters.

At the Washoe smelter, Anaconda, Mont., the normal working is to blow the matte to white metal, pouring off slags when necessary; then to blow up to blister copper, and pour the resulting metal in regular sequence.

The matte here averages 45 per cent. copper; about 8½ tons are charged at an average temperature of 900° C., with the converter in an upright position and with the blast of 16 pounds per square inch. A few lumps of coal are thrown in before and during the running in of the matte.

During this charging, copious and heavy white fumes and smoke and a full red to red-brown flame are emitted—this effect being, as previously stated, partly due to zinc, lead, or arsenic fumes, to sulphur and iron burning, and to the effect of coal on the flame.

The converter being turned slightly back, the blow proper commences. The flame has dropped to some extent, and continues red to red-purple for from 2 to about 8 minutes, after which green commences to show in the red smoky flame, when the first or slag-forming period properly begins.

The green becomes more and more prominent until the flame is altogether of a vivid apple-green color after about 15 minutes blowing. It is also brighter, fuller, and is accompanied by plenty of smoke; slagging of the iron being now in full operation and the metal very hot.

After some 40 to 45 minutes' blowing (depending largely upon the working conditions) flashes of blue appear occasionally in the flame. These gradually increase in number and finally the flame becomes white-blue.

This is a sign that most of the iron has been slagged off, that the white metal stage has been reached and that copper silicate is being produced, to which latter fact the color of the flame is to be attributed. The copper oxide now being formed appears to produce the silicate in presence of much slag rather than attack the copper sulphide, especially if the temperature be high.

The fact that the marked green and blue color effects are due to the formation of silicates of iron and of copper is interesting; these colors are not produced unless the respective oxides are being slagged.

When this white metal stage has been reached, the slag is poured off until an iron rake held under the stream begins to show signs of metal (which gives an appearance of spots of grease on the blade).

If considered necessary, a "dope" charge of scrap, cleanings, and silicious materials, etc., is now added—partly to cool the charge—then the converter is turned up and blowing resumed. Very often a preliminary skimming is carried out to prevent too great an accumulation of slag before the white metal stage is quite reached and while the flame is green, but giving indications of blue. Blowing is afterwards continued, the pure apple-green flame results, and white metal is eventually obtained. The first stage of the blow to white metal occupies about 60 minutes.

The second part of the blow commences with a vivid red-brown flame and smoke; but this gradually decreases and a thin red-purple flame of some brightness with thin smoke results and continues with very slight change to the end of the operation.

The temperature of the operation can be judged by the flame, a red-brown indicating the correct temperature. If too red, the metal is too cold and coal is thrown in; if the tint be too orange, the metal is too hot and "dope" is charged.

The end of the blow is most difficult to judge, the size and color being some criterion; but a very important guide is the emission of little shots of copper which no longer stick to the hood over the converter, but rebound from it. This is the stage where the judgment and skill of the skimmer is most tried. The metal is further tested by judging the appearance of a small quantity poured on to the floor; a rugged and uneven surface is satisfactory. The second period of the blow takes from 60 to 75 minutes.

Below are given observations made during a blow:

Converter A.—Matte charge. Charged 2:25 P. M., flame red; 2:29 P. M., green appears; 3:00 P. M., green becoming brighter; 3:17 P. M., vivid green; 3:18 P. M., skimmed, no metal reached; 3:21 P. M., blue appears in flame; 3:27 P. M., flame chiefly blue. Converter turned down to skim. Doped.

Converter B.—White metal charge. Charged 4:13 P. M., doped; 4:14 P. M., converter turned up; flame red; 4:16 P. M., flame red-purple; 4:18–5:20 P. M., flame peach to bronze-purple color.

The changes in composition of the metal during a blow have been shown graphically in a paper* by Mr. E. P. Mathewson, superintendent of the Washoe smelter at Anaconda, Mont.

The changes in the appearance of the flame during Bessemerizing are striking, and each has its own significance in connection with the various stages of the process. Their reproduction in color may assist in the realization of such effects which a verbal description could not convey.

The colors mentioned are representative of the reactions which occur in converting a fairly pure iron-copper matte when blowing with a high pressure. With low pressure the density of the colors is much lessened, and in addition, the presence of lead and zinc increases the luminosity of the flame.

Mr. W. A. Heywood says that "if nickel be present the color of the flame is bright green from start to finish, yet the man in charge of the converter is able to determine the finish of the blow by the appearance of the flame, regardless of the color."

Mr. Charles Olden says that "the coloration of the flame differs at various operations" and suggests that in addition to judging the end of the blow by flame coloration and the emission of shots of copper, rod sampling by the usual method should be followed.

"This would be as efficient and less troublesome than pouring a small quantity of the molten mass on the floor.

"The three tests would tend to prevent 'burning' and much wear and tear on the converter."

PREVENTION OF SCALE IN BOILERS

It has been discovered by a man in Hanover, Germany, that if hard water, previous to being fed into a boiler, were allowed to run over a plate of aluminum set at an angle and exposed to sunlight or diffused daylight, no scale would be formed through the action of such water on the boiler plates or tubes. The solid matter contained in the water deposits as a fine mud, which is easily removable on the lowest part of the boiler, consequently the tedious process of chipping off the scale is obviated. This process was tried at the Proprietary Company's Port Pirie Works, Broken Hill, Australia. Two plain aluminum sheets, each 4 feet by 2 feet were fixed in a frame inclined at an angle of 59 degrees, facing the sun. Water from the main was then allowed to flow over the plates from a perforated pipe fixed at their upper edge. A sufficient quantity of the water was run over the plates in the day time and stored to supply a Lancashire boiler for 24 hours. Mr. J. H. F. Hill, responsible for this treatment, states that the cause of the phenomena described has not been ascertained.—*Australian Mining Journal.*

THE MAMMOTH CAVE OF KENTUCKY

Written for Mines and Minerals, by James H. Gardner

The Geological Formations and Natural Conditions By Which the Cave Was Formed

The Mammoth Cave is in Edmonson County, Western Kentucky. This cavern is one of the most widely-known objects of general interest to Europeans traveling in America, and it is said that in this country the percentage of people who have heard of the cave increases directly with the distance from it. It is a fact that natives living within 10 miles of the cave cannot direct one to it and others living much closer have never gone into it.

This section of Kentucky is noted for its natural rock houses, sink holes, and subterranean caverns. It is a limestone region and one especially favorable to the process of cave making. The drainage of this part of Kentucky is chiefly beneath the surface and one may at places travel 20 or 30 miles without crossing a surface stream. The prevailing topography consists of funnel-shaped basins 40 to 190 feet deep and draining 5 to 2,000 acres. Water collecting from gullies meandering out over these circular divides is drained by means of sink holes 3 to 15 feet in diameter, which communicate downward with underground channels. By this means the water is led off through subterranean streams to the major water courses where it emerges either at the edges of the valleys or else rises in the form of a spring beneath the main stream.

VIEW IN MAMMOTH CAVE, SHOWING ACTION OF WATER

The Mammoth Cave is in what is generally known as the St. Louis limestone of the Mississippian series, which, farther west in the state, Ulrich has divided into the Spergen, the St. Louis, and the Ste. Genevieve. In the Cave district, these limestone beds aggregate a thickness of about 500 feet. On the higher hills and ridges the limestones are capped by outliers of Chester sandstone, which is in turn overlain unconformably by a conglomerate sandstone corresponding to the Mansfield formation of Indiana and possibly in part with the Lee conglomerate of Virginia, Tennessee, and East Kentucky. The St. Louis is the lowest of the formations exposed in the section under discussion. It has a gentle westerly dip and outcrops over a wide area northeast, east, and southeast of the Mammoth Cave; an area abounding in smaller caverns. The relation of these formations to one another and to Green River which drains the district has an important bearing on the origin of the cave.

Origin of the Cave.—There is little doubt that the cave has originated in a most quiet and orderly manner and that the natural forces now at work enlarging it are the essential ones that have produced it. This view is at variance with the opinions advanced many years ago by Prof. Alexander Winchell and Prof. E. D. Cope. An abstract of theories made by Professor Winchell and given in Packard and Putnam's publication on the fauna of the cave,* 1872, is as follows:

"The country of the Mammoth Cave was probably dry land at the close of the coal period, and has remained such, with certain exceptions, through the Mesozoic and Cenozoic ages, and to the present. In Mesozoic times, fissures existed in the formation, and surface waters found their way through them, dissolving the limestone and continually enlarging the spaces. A cave of considerable dimensions probably existed during the prevalence of the continental glaciers over the northern hemisphere. On the dissolution of the glaciers, the flood of water which swept over the entire country, transporting the materials which constituted the modified drift, swept through the passages of the cave, enlarging them, and leaving deposited in the cave, some of the same quartzose pebbles which characterize the surface deposits from Lake Superior to the Gulf of Mexico. Since the subsidence of the waters of the Champlain epoch, the cave has probably undergone comparatively few changes. The well, 198 feet deep, at the farther end of the cave, shows where a considerable volume of the excavatory waters found exit. The Mammoth dome indicates probably, both a place of exit and a place of entrance from above. So of the vertical passages in various other portions of the cave."

Again Professor Cope's "general observations" in his article on the Port Kennedy fauna is quoted as follows:

"The origin of the caves which so abound in the limestones of the Alleghany and Mississippi valley regions, is a subject of much interest. Their galleries measure many thousands of miles, and their number is legion. The writer has examined 25, in more or less detail, in Virginia and Tennessee, and can add his testimony to the belief that they have been formed by currents of running water. They generally extend in a direction parallel to the strike of the strata, and have their greatest diameter in the direction of the dip. Their depth is determined in some measure by the softness of the stratum, whose removal has given them existence, but in thinly stratified or soft material, the roofs or large masses of rock fall in, which interrupt the passage below. Caves, however, exist when the strata are horizontal. Their course is changed by joints or faults, into which the excavating waters have found their way.

"That these caves were formed prior to the Postpliocene fauna is evident from the fact that they contain its remains. That they were not in existence prior to the drift is probable, from the fact that they contain no remains of life of any earlier period so far as known, though in only two cases, in Virginia and Pennsylvania, have they been examined to the bottom.

* Packard, A. S. Jr., and Putnam, J. W., editors *American Naturalist*, "The Mammoth Cave and Its Inhabitants," Naturalist Agency, Salem, 1872.

No agency is at hand to account for their excavation, comparable in potency and efficiency to the floods supposed to have marked the close of the glacial period, and which Professor Dana ascribes to the Champlain epoch. An extraordinary number of rapidly flowing waters must have operated over a great part of the Southern States, some of them at an elevation of 1,500 feet

Entrance to Mammoth Cave, from Inside

and over (perhaps 2,000) above the present level of the sea. A cave in the Gap Mountain, on the Kanawha River, which I explored for 3 miles, has at least that elevation."

These views are excusable on the ground that at that time the boundaries of North American glaciation and the areas covered by the drift were not known. But glaciation little more than crossed the drainage of the Ohio, and outwashed material never reached the drainage of Green River this distance above its mouth, hence the views of these eminent men have now become untenable. The quartzose pebbles found in the cave by Professor Winchell and mistaken for glacial pebbles are those which are secondary from the conglomerate sandstone and have been washed into it from the immediate vicinity. His mistake was a natural one: that of drawing a general conclusion from insufficient observation. The same may be said of the conclusion of Professor Cope.

The rocks in the vicinity of Mammoth Cave are very slightly disturbed and such a condition is necessary for the formation of large caverns. A thick massive terrane of limestone beds, slightly above drainage and to some extent jointed or fractured, presents the proper relations for the genesis of such a cavern as the Mammoth Cave. It is at once evident from a study of the cave and surroundings that dynamic forces have played their part in the creation of the cave only by producing the initial fractures or joint planes through which acidulated waters found their way downward to the level of Green River. The first stages in the growth of Mammoth Cave were brought about by percolation of ground water through joint planes probably developed by those forces which produced the Cincinnati Arch or perhaps to some extent by the subsequent settling of that structure.

In Kentucky and the adjacent states of Ohio and Tennessee, the writer has observed that the rocks having dips normal to the Cincinnati arch usually show a decided joint structure. The lead- and zinc-bearing veins of the "Blue Grass" section of the state occupy fissures roughly parallel to the axis of the fold and the writer has observed that the major jointing on both sides of this anticline for a long way back from the axis has as a rule a trend slightly east of north and west of south. These fractures are especially noticeable in the Devonian shales of Eastern Kentucky and at places are equally prominent in the rocks of the Mammoth Cave region of Western Kentucky.

It was from meteoric waters slowly traversing these joints in the massive limestones that the cave had its origin. The same holds true for the thousands of other caves in the area of outcrop of the St. Louis and Ste. Genevieve limestones west of the Cincinnati arch. The Newman limestone occupying a similar stratigraphic and structural position east of the arch is also a cavernous formation.

Geologically speaking, the Mammoth Cave is comparatively young, Green River, in modern geologic time, has cut through the Chester sandstone to a depth of about 200 feet into the underlying limestone. The cave action began when the river channel was lowered into the limestone. Ground water passing down through the smallest joints of the stone, then slightly above the level of the river, began the solution of what is now the uppermost levels of the cavern. These waters congregated along planes of least resistance to form Echo River which by both solution and erosion has been the secret of the immensity of the cave's development. This stream now flows in the deepest levels of the cave and empties into the waters of Green River. Echo River is now about 195 feet below the highest levels of the cave, which is approximately the vertical distance that Green River has cut into the limestone. The present entrance of the cave is in the east bank of Green River near the top of the limestone and is probably the original exit of Echo River. From time to time the course of Echo River has been changed by its waters finding a lower outlet, thus causing the stream to abandon its former levels. In this way the various avenues in the higher and dryer portions have been formed. In conjunction with the solvent and erosive action of the river are the effects of various tributary rivulets and floods from torrential rains. The various pits and domes are the products largely of the erosive action of flood water fed into the cave from the basin-shaped sinks on the surface. The destructive effects of this water are in some cases increased by the grinding action of pebbles inherited from disintegration of the conglomerate of the surrounding hills, chert fragments resulting from disintegration of the limestone. But it is the slow action of perennial waters that has been the chief agent in the growth of the cavern. The district is covered by a luxuriant growth of vegetation and it is from the damp humus of this forest that water charged with carbon dioxide finds its way into the subterranean channels, converting the limestone into soluble bicarbonate of calcium, the greater amount of which is carried

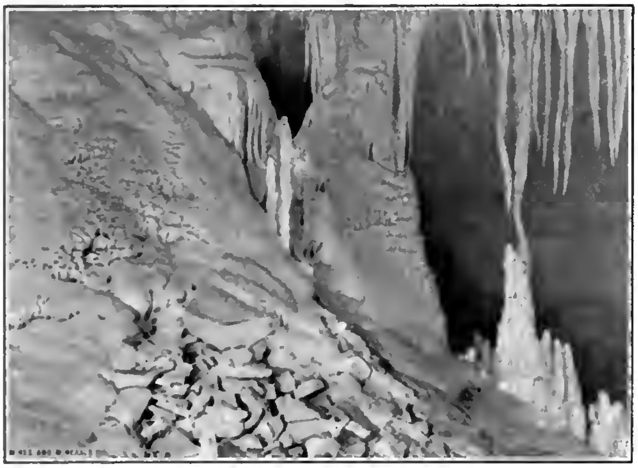
On Echo River

out via Echo River, but a portion of which is precipitated in the form of encrustations, stalactites, stalagmites, and pillars. This precipitation is found chiefly in the higher and drier portions of the cave where the waters are stronger in acid content and where evaporation is greatest.

The time required for the cutting of Green River to a depth of 195 feet into the limestone represents the age of the cave.

At the rate of 1 foot in 6,000 years (the estimate of removal of sediment from the Mississippi Valley) this gorge would have been cut in slightly over 1,000,000 years. If from this is deducted the more rapid cutting in upland streams, the calculation is brought to considerably less than 1,000,000 years, which according to Professor Shaler's estimate of geologic time, would probably not extend beyond the Pliocene.

Fauna.—The fauna of the Mammoth Cave is undoubtedly recent. For a time the subject of the blind fishes, insects and crustacea of this and similar caverns led to heated arguments in the application of the Darwinian and Lamarckian theories of evolution. But it is now generally conceded that these aberrant forms of life are specialized derivatives of the ordinary fresh-water or land fauna. The organs affected by the life of darkness are those directly concerned with the phenomena of the outer world, chiefly those of sight. The important modifications brought about by this change from light to darkness have led to the origin of new species by change of environment. The resemblance of the underground forms to those of the outside compares too closely for application of the theory that supposes these species to be the result of internal tendencies. Such organs as the eyes of fishes have been developed through the geologic ages from beyond the Silurian, yet in the comparatively short interval of the cave's formation these organs have



Stalactites and Stalagmites

not only lost their functions but nearly disappeared. There are two kinds of blind fishes in the Mammoth Cave, the smaller of which is slightly over 1½ inches long, the *Typhlichthys subterraneus.* The larger, slightly over 4½ inches long, the *Amblyopsis spelaeus.* In 1853, Professor Agassiz took a tour of the southern and western states and at that time wrote a letter to Prof. D. James Dana stating that he had discovered a new fish genus. This genus he named "*Chologaster*," giving the specific name "*cornutus*." This fish has eyes and is not a cave type, being found among the ditches of the South Carolina rice fields. It is much like the blind fishes of caverns, and a species named by Putnam, "*Chologaster Agassizii*," appears to be an intermediate type. The latter was obtained from wells of Tennessee and Alabama. There is little doubt that these types are closely related and show the transition in specific character from those of open surface waters to those living in constant darkness.

The crawfish, *Cambarus pellucidus*, first described by a German, Doctor Tellkampf, has very rudimentary eyes in the adults but larger in the young. This seems to be an evidence that the embryo develops like that of other species and that blindness is due to their physical surroundings and adaption to changed conditions of life. Specimens taken of the crawfish, *Cambarus Bortonii*, are not blind but have well-developed eyes and, one may assume, have been recently introduced into the cave.

What is commonly known as the cave cricket, *Hadenoecus subterranea*, offers another plain case of the effects of environment. The wingless locust, *Ceuthophilus maculatus*, which inhabits the outer world and lives ordinarily under stones is probably the ancestral type of *Hadenoecus subterranea.* Its legs have grown longer because of its life of clinging to walls, its antennae and palpi have elongated and become more sensitive organs of touch and hearing, and its body has partially bleached.

A small isoped crustacean, *Coecidotea stygia*, inhabits the cave and is closely allied to certain species which are all marine with the exception of two species which inhabit deep lakes. This similarity may be accounted for by the somewhat similar condition as regards light and temperature in caves and deep waters.

Within the cave are also small blind spiders, blind beetles, and a blind, hairy myriapod, *Pseudotromia Vudii.* Besides the blind myriapod here named, there are other species of "thousand legs" present that have eyes.

Hymenoptera and Memiptera are not represented in the cave. The flies or Diptera are represented by a few species with eyes, living in sections of semidarkness. The total of the cavern fauna includes, so far as known, 4 genera of infusoria, 2 vermes, 5 crustacea, 12 arachnida, 17 insecta, 1 mollusc, and 8 vertebrates.

GEOLOGIC PHENOMENA OF THE CAVE

Air-Currents.—At the entrance of the cave one notes a very perceptible air-current. This current flows out of the cave in summer and into the cave in winter. Its explanation is simple and is the result of equalization of air pressure due to differences in temperature of the outside and inside air. In summer the air in the cave is cooled by contact with the rocks and therefore heavier than the air outside and by gravity rushes out of the mouth. This has a tendency to produce a vacuum which is filled by warmer air drawn into the cave through its highest openings communicating with the surface. In winter the movement is reversed because the air within the cave is warmer than the exterior air and flows out of the highest opening to be replaced by cold air rushing in at the lower ones. The temperature of the cave is uniform at about 54° F. the year around, which is the same as that of Wyandot and Luray caves.

Calcium Nitrate Deposits.—Near the Mammoth dome, not far from the entrance of the cave, are deposits of calcium nitrate formed by leaching of water containing calcium carbonate in solution, through guano of bats. In this portion of the cave thousands of bats congregate to spend the winter. This calcium nitrate was used in the manufacture of gunpowder in the war of 1812. The nitrate was dissolved and leached through wood ashes in order to convert into potassium nitrate which was crystallized and sent by pack mules to the Ohio River.

Stalactites and Stalagmites.—Water charged with bicarbonate of calcium precipitates in the upper levels of the cave through evaporation, forming calcite onyx and structures common to limestone caverns. Drops of water so charged remain by adhesion on the ends of stalactites long enough to permit of evaporation which is stimulated by the currents of air through the cave. When a drop falls to the floor it is broken into spray thus increasing evaporation and further precipitation which builds up stalagmites from below.

Gypsum.—The origin of the gypsum crystals which line the walls and sides of certain portions of the cave is explained by the presence in the unweathered limestone of iron pyrites nodules. By exposure to air and moisture, the iron and sulphur are oxidized producing sulphuric acid and iron oxide; then a double decomposition takes place; the sulphuric acid acts on the limestone, forming gypsum and liberating carbon dioxide, which unites with the iron oxide producing iron carbonate. On further exposure the iron carbonate parts with carbon dioxide leaving a brown coating of iron oxide. These crystals of gypsum grow outward from the pyrites nodules, often forming beautiful crystal rosettes.

THE DESICCATION OF FURNACE AIR

Written for Mines and Minerals

Comparative Results of Refrigeration Methods and by Use of Calcium Chloride

In a general way the readers of Mines and Minerals are familiar with the Gayley dry air blast which has accomplished such economies in iron blast-furnace practice by the device of refrigerating and drying air. Many thousand tons of air are forced into a blast furnace daily, each pound of which contains a small weight in moisture depending on the weather conditions. The moisture thus carried into the furnace decreases the heat of the furnace and necessitates the use of more fuel to perform a given amount of useful work. Mr. Gayley, by passing the air through a refrigeration device precipitates the moisture, after which the air is passed through the hot-blast stoves and then to the furnace. By this arrangement not only is there an economy in fuel, but the output of the furnace is materially increased.

In the April issue of the *Compressed Air* magazine there is an article on "Successful Air Cooling and Drying" from which is abstracted the data and diagram relative to the Gayley process.

The data here presented are furnished by Mr. Gayley from a western plant for the month of July, 1910. The summer months represent the period of greatest humidity and highest temperature, and for that reason they furnish the best opportunity for demonstrating the efficiency and value of the process. While the atmosphere, as shown by the figures, varies widely in both temperature and moisture, the variations in the dry air are within narrow limits, and approach as close to uniformity as seems possible to obtain in a mechanical device that is treating 40,000 cubic feet of air per minute.

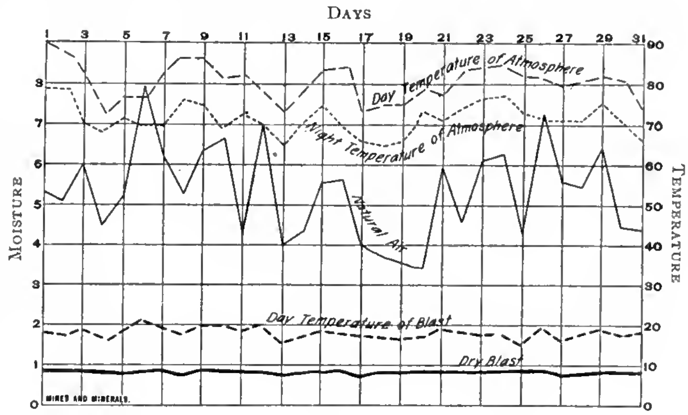


Fig. 1

The amount of work done by a dry-air plant in midsummer in removing moisture is ordinarily not fully comprehended by simply expressing the moisture content in grains per cubic foot of air. Taking, for example, a very humid day, July 6, when the moisture as shown in Table 1, averaged 7.90 grains for the day and night, there would have entered the furnace under natural air conditions 7,797 gallons of water in the 24 hours. This would be the equivalent of 185.6 barrels. The dry air on the same day contained only .86 grain, and the quantity of water entering the furnace was accordingly reduced to 849 gallons, thereby eliminating 6,948 gallons, and saving the fuel necessary to dissipate it. Taking again the day with the lowest humidity, July 19, when the moisture for day and night averaged 3.45 grains, the furnace would have received 3,410 gallons of water, but the dry air carried is only 809 gallons, representing an abstraction of 2,601 gallons. Thus, even on days of relatively low humidity, the quantity of water extracted is very large.

The amount of water extracted through the dry-air process expressed in gallons as seen in Table 2 is very impressive, and will be particularly appreciated by practical blast-furnace managers who are familiar with the cooling effect produced in the furnace hearth from a small leak from a tuyere or bosh plate. The diagram, Fig. 1, shows graphically the grains of moisture in the atmosphere and the resulting dry air. The uniformity of the dry air speaks for itself, as to its value in a process so delicate in adjustment and so variable as a blast furnace.

When the results of dry air were first made public in 1904, it was thought by some that the economy obtained was not due so much to low moisture in the dry blast, as to creating conditions of uniformity in the moisture—that is, if the moisture was maintained uniformly at 2 to 2.50 grains or 3 grains, the results would be practically as good as if it was reduced to 1.5 grains. This, however, does not appear to be borne out in actual practice, as the best results are obtained when the moisture is reduced below 1 grain per cubic foot of air, and is markedly greater at .75 grain than at 1.50 grains. The reasons for this do not seem at present to be clearly understood, although it has been demonstrated in practice.

The conclusion reached from the experience of the past 6 years is that dry-air blast conservatively considered will effect a saving of 10 per cent. in fuel, with an increase in output of 12 per cent., and the product can be increased beyond this at the expense of fuel saving, and vice versa. The tendency in some cases is to increase the output at the expense of fuel saving.

At one blast furnace the saving in coke was 7.5 per cent. on dry air, but concurrently the output was increased by 23 per cent. Thus the dry-air blast not only reduces the cost of pig iron, but it also creates uniformity in the furnace operations, and any cheapening of the pig iron cost is reflected to a greater extent in the finished steel product.

It is not necessary to offer any explanation of the diagram, which speaks for itself, except to call attention to the fact that the moisture scale is at the left hand and the temperature scale at the right hand.

Owing to the success met by Mr. Gayley, it was but natural that others should turn their attention to accomplishing similar results in some other way. Messrs. Felix A. Daubine and Eugene V. Roy conducted experiments on the drying of air by calcium chloride,* the results of which were so satisfactory that their process was installed at the Differdange Steel Works, Luxemburg. In a recent paper read before the Iron and Steel Institute a description of the Luxemburg plant was given and here reproduced.

It is inherent in the very nature of bodies that every substance the solutions of which, when highly concentrated, possess very low vapor tensions, should be, for that very reason, a hygroscopic substance, and capable of serving for the extraction, up to a certain state of equilibrium, of the moisture contained in atmospheres possessing higher vapor tensions than those of the solutions in question. The word "solution" should, in this connection, be understood in its most general sense—a solution of a given strength of concentration may be solid or liquid, this being a matter of temperature—and it will be seen later that one of the characteristics of the process is the maintenance of the solutions obtained in this solid "phase."

The more rapidly equilibrium is attained, the more suitable is the substance for playing its part as a desiccating agent. A highly hygroscopic body, at a given degree of concentration, would possess very low vapor tensions, differing greatly from the vapor tension of the air to be desiccated. This is precisely the case as regards chloride of calcium and certain of its hydrates, the very low vapor tensions of which permit rapid desiccation. In this connection the properties of calcium chloride have been known for a very long period.

It should also be noted that every external influence which is capable of lowering the tensions of the hydrates favors, by this very fact, the desiccation; and as, for any given hydrate,

* Journal of the Iron and Steel Institute, Vol. I, 1910, pages 613-615.

these tensions vary with the temperature, and in the same proportion, it follows that the lowest temperature possible should always be selected. Further, as the vapor tensions increase in proportion as the molecules of water absorbed

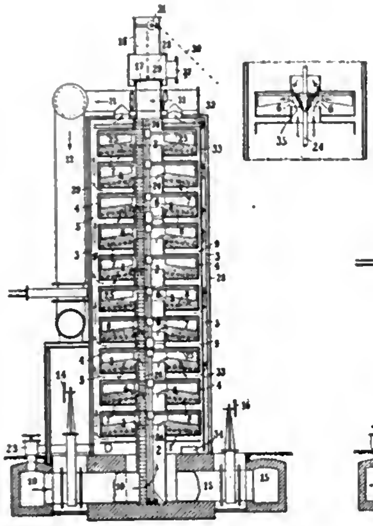

Fig. 2

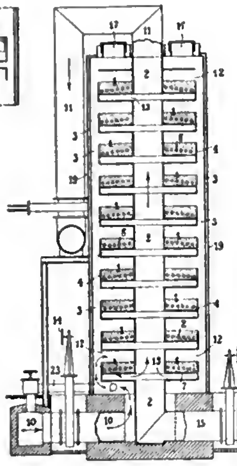

Fig. 3

render the dilution of the hydrates greater, it becomes equally necessary always to maintain the solution at a sufficiently high degree of concentration.

Consideration of these principles, taken together with numerous experiments, has enabled the authors to determine the economic conditions of the evolution of calcium chloride during the course of its periods of hydration and regeneration.

The problem at the Differdange works was to desiccate the air blast for a furnace of 150 tons daily capacity and at the same time realize the economies obtained in the Gayley process. Two forms of apparatus were designed, both of which are shown in section in Figs. 2 and 3. In the first design, Fig. 2, the blast enters through a central well and is distributed through openings to the various compartments containing calcium chloride. On escaping from these compartments the blast is collected in an annular chamber, whence it is led to the place where it is to be utilized. In the second design, Fig. 3, the blast enters an annular chamber and is collected in a central reservoir after traversing the layers of calcium chloride.

In order to regenerate the calcium chloride for reuse, the central reservoir or annular chamber is connected with hot-air pipes that admit gases to remove the excess moisture from the chloride of calcium. It having been found by experiment unsatisfactory to have a dilution of more than 8 parts of water this part of the apparatus requires attention.

Table 2

July, 1910	With Natural Air Gallons	With Dry Blast Gallons	July, 1910	With Natural Air Gallons	With Dry Blast Gallons

Equivalent in barrels of 42 gallons each				3,918	601

In Figs. 2 and 3 the same numbers refer to the same parts. The compartments represented by *1* contain the $CaCl_2$; *2* is a central shaft; *3* is a cover, which forms with the external shell; *4* a number of compartments; and *5* is the annular chamber.

Each compartment *1* has a circular inlet orifice *6* and a grid *7*, on which the chloride of calcium rests. An outlet *9* is provided below the grid.

Toward the end of the desiccation the air is drawn by means of the fan across the main lead *10* into the central shaft *2*,

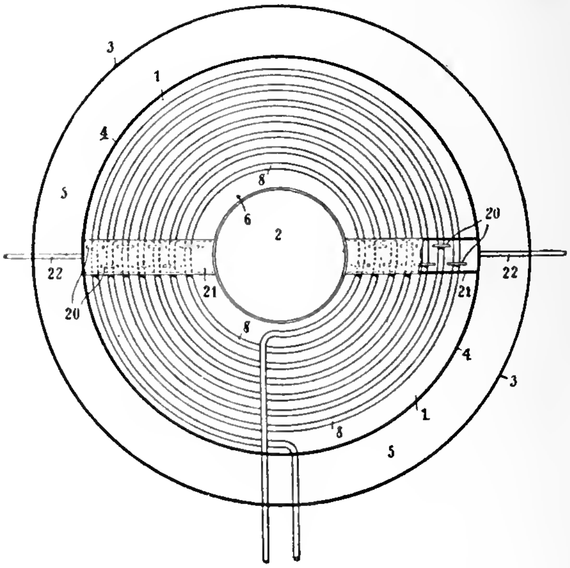

Fig. 4

and distributed to all the compartments. It traverses the chloride of calcium from above downwards, depositing its moisture; it then escapes into the annular chamber and reaches the conduit pipe *11*, which takes it to the place of utilization.

The chloride of calcium warms during the desiccation, and

this must be rectified by the cooling. It is with this object that water is made to circulate in the spirals, shown in Fig. 4, provided in each compartment. These spirals are arranged to have a certain inclination to provide for their being rapidly emptied. The joints are effected in a special box securing a water-tight separation for the chloride of calcium, with a discharge vent in case the joint becomes defective. The chloride is thus completely protected against such an event occurring.

When the chloride of calcium has absorbed the requisite amount of moisture, the apparatus is cut off from the inlet and outlet of air by the slide valve *14*, and communication is made by means of the slide valve *16* with the main *15* which conducts air or warm gases. As the temperature should only be increased gradually, the fan aspirates cold air at the same time as it takes in the gases to allow of the temperature being regulated. By diminishing the quantity of air, and increasing that of the gas, the temperature is gradually raised to 235°. The object of this is to maintain the hydrates in their solid form and in the course of this regeneration the temperature should not exceed 235°. When the calcium chloride has been regenerated, the apparatus is first cooled by means of a cold current of air entering chamber *5*, by the conduit pipe *23*, and escaping by the outlet *17*, and then water is introduced in the spiral cooling coils until the temperature has been sufficiently lowered. The apparatus is then ready to desiccate the air blast anew.

In the installation shown in Fig. 5 three apparatuses are employed, one of which dries the blast, while in the second the chloride of calcium is being regenerated, and the third is undergoing cooling. During the period of the passage of the blast or at the end of the period of cooling, it is possible to obtain access to the appliance either by the central shaft by means of the ladder shown in Fig. 2, or to the annular chamber by the ladder *33* running on rails at the top of *32*.

In the application of the process at Differdange, which is shown in Fig. 5, the conditions require the drying of 30,000 cubic meters* of air hourly. The apparatus was constructed in accordance with Figs. 2 and 3 and possess the following features:

Total area presented to the passage of the blast, 100 square meters per apparatus. Number of compartments, 10.

Depth of the layer of calcium chloride in each compartment, 24 centimeters.

It may be well to explain that 240 kilograms of calcium chloride spread out in a layer, 24 centimeters in depth, on a square meter of surface, will desiccate 300 cubic meters of air, per hour for 4 hours under average conditions of 15 grams of moisture per cubic meter.

Apparent density of the chloride of calcium.

Weight of chloride of calcium contained in each apparatus, 24,000 kilograms.

Weight of chloride of calcium in all three appliances, 72,000 kilograms.

Cooling surface of the spirals in each apparatus, 170 square meters.

These appliances have been designed to work in the most unfavorable conditions, that is to say, to remove during the summer months 15 grams of moisture per cubic meter of air during a period of 4 hours.

* 1 cubic meter = 35.315 cubic feet.

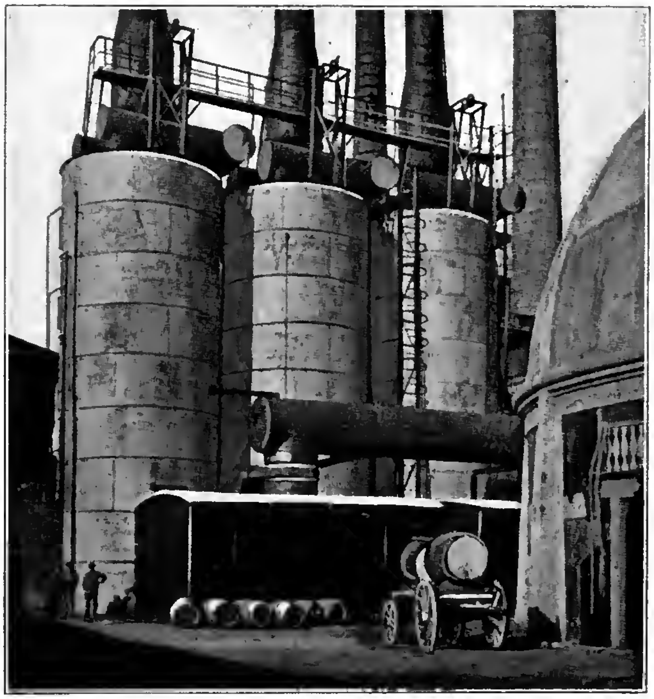

FIG. 5. AIR-DESICCATING APPARATUS

At the time of writing this paper the appliances had been working normally for 6 weeks, but as the season is the end of winter, and as the moisture in the air is not very abundant, it has been found unnecessary to make as many reverses as were contemplated. Each apparatus receives the blast from 6 to 8 hours. The air which contains 6 to 8 grams of moisture before its passage only contained from 1 to 15 grams per cubic meter on emerging from the apparatus, and this figure remains practically constant from the commencement to the conclusion of the period.

Regeneration requires 4 hours for its completion, and is carried out by means of the waste smoke gases from boilers and from Cowper stoves. These gases, cleaned to the extent of .4 gram per cubic meter, pass directly through the mass of chloride. The temperature is regulated at 30° to commence with, and thereafter gradually raised in conformity with a certain ascertained law up to about 200°. In the summer the temperature will be carried to 275°.

Cooling takes 3 hours.

It is interesting to compare these results of drying the blast with those which are capable of being given by the freezing method used by Mr. Gayley.

In Table 3 the authors reproduce the vapor tensions of ice and the amounts of moisture which saturate a kilogram of dry air at temperatures below 0° C.

From this table it may be seen to what temperature the air must be cooled to obtain results identical with those obtained at the Differdange Steel Works.

At 15° an amount of humidity of 1.5 grams per cubic meter corresponds with the content of 1.22 grams per kilogram of dry air. This figure, as may be seen, is well within the limits of the foregoing table. To obtain this result, calculation shows that it is necessary to cool the air effectively to −15°, which requires even considerably lower temperatures in the refrigerating tubes.

TABLE 3

Temperatures Degrees C.	Vapor Tensions in Millimeters of Mercury Per Cent.	Weight of Water Vapor in Grams in Saturated Air Per Kilogram of Dry Air Per Cent.
0	4.60	3.80
− 1	4.27	3.50
− 2	3.95	3.20
− 3	3.66	3.00
− 4	3.39	2.80
− 5	3.13	2.60
− 6	2.89	2.40
− 7	2.67	2.20
− 8	2.46	2.00
− 9	2.27	1.85
−10	2.09	1.70

This shows the advantage which the employment of calcium chloride has over that of refrigerating machines. While, with the latter system, cooling to −5° leaves a minimum of 2.60

grams per kilogram of dry air, the use of the calcium chloride regenerated under the form $CaCl_2+1$ to 2 parts H_2O and maintained in sufficient excess, at 15° allows of a degree of moisture as low as .5 gram per kilogram of dry air being attained.

In the winter months, during which the refrigerating system is practically inoperative, particularly in Continental localities, chloride of calcium allows of exceedingly low figures being attained—that is, distinctly less than 1 gram per cubic meter of air.

The installation is too recent for the true value of the economies to be stated, but it is established that the manufacture of dry air need present no difficulty whatever.

The installation has cost a little less than one quarter of what would have been the cost of an installation for desiccation by means of refrigerating machines. One man for the day shift and one for the night shift are sufficient to handle the apparatus, which is of the most simple description. The expenses of working are thus greatly reduced.

The authors state, in conclusion, that similar apparatuses are under investigation, not only for other metallurgical works, but also with a view to their application in other industries, that require drying operations carried out at low temperatures, as, for example, for the desiccation of chemical or pharmaceutical products, india rubber, resins, gums, gelatin, albumen, glue, aniline colors, and various organic bodies. It may thus be seen that there is a vast field open for the commercial production of dry air.

PERSONALS

John J. Lincoln, General Manager of the Upland Coal and Coke Co., Elkhorn, W. Va., had the American Institute meeting, the class day at Lehigh, and a business meeting in Philadelphia so arranged he could attend them all on one trip.

J. C. Welch has resigned as smelter manager for the East Butte Copper Mining Co., at Butte, Mont.

Edwin Ludlow, former general manager of the Mexican Coal and Coke Co., is now manager of the New River Collieries Co., with headquarters at Eccles, W. Va.

George A. Shroter, consulting engineer of the Mines Company of America, has returned to New York from Mexico.

Norman Fraser has resigned from the Crow's Nest Pass Coal Co. to take the management of the German American Development Co. in the Brazean fields, Alberta.

E. M. Thornby, E. M., of Los Angeles, Cal., has returned after a three months trip of inspection for English gold mine seekers.

Hood McKay, for a number of years connected with the Susquehanna Coal Co. as superintendent of Summit Branch Mining Co., Lykens, Pa., and district superintendent of Lehigh Coal and Navigation Co., Lansford, Pa., has been elected president of the O. S. Richardson Coal Co., with headquarters at Chicago.

Luther W. Balmey, assistant professor of mining and metallurgy at Leland Stanford University, has been appointed to a similar position at Sheffield Scientific School of Yale University.

M. L. O'Neale has been appointed superintendent of the Seaboard Coal and Coke Co.'s mines at Coal City, Ala.

Geo. I. Adams, formerly with the United States Geological Survey, later in the Philippine Bureau of Mines, and more recently in Peru, has returned to the United States, where he will continue his professional career as geologist. His present headquarters are at Washington, D. C.

Reese Hammond, formerly with the Lehigh & Wilkes-Barre Coal Co., has accepted the position of mine foreman with the American Gypsum Co., of Akron, N. Y.

J. B. Tyrrell, mining engineer, of Toronto, Can., and one of Canada's leading explorers, is writing on a new edition of Samuel Hearne's Diary and David Thompson's Journal.

Harwood Frost has severed his connection with the *Engineering News* and is now located at 226 La Salle Street, Chicago, Ill.

G. S. Rice, of Pittsburg Testing Station; Erskine Ramsey, of Birmingham, Ala.; A. B. Jessup, of Wilkes-Barre, Pa.; H. M. Warren, of Scranton, Pa.; and John Bart, of Windber, Pa., sailed from New York June 16, to study European safeguards against mining accidents and investigate the mining methods abroad.

LEHIGH UNIVERSITY GRADUATES

The subjects of theses presented by candidates for degrees in mining, metallurgy, and electrometallurgy at June, 1911, commencement at Lehigh were as follows:

FOR THE DEGREE OF ENGINEER OF MINES

Horace Daniel Bleiler (with P. N. Lopez), Frackville, "The Cyanide Process."

William Ewart Fairhurst (with G. R. Wood), Paterson, N. J., "The Cyanide Process."

Pedro Nicolas Lopez (with H. D. Bleiler), New York, N. Y., "The Cyanide Process."

Carl Weaver Mitman, B. A. (Lehigh University), South Bethlehem, "The Pre-Cambrian Limestones in Pennsylvania."

Charles William Rauch, Bethlehem, "The Oxford Furnace, N. J., Iron Mines."

Louis Allgaier Rehfuss, Philadelphia, "Proposed Plans for the Development of a Mexican Mine."

James Humble Smith, Jr., Mount Carmel, "Development of Bituminous Coal Property in Kanawha County, W. Va."

Felix Frank Trotter, Jr., Albuquerque, N. Mex., "Flow of Underground Water at the Friedensville Zinc Deposit."

Leon Wittgenstein, Louisville, Ky., "Magnetic Ore Concentration."

George Reid Wood (with W. E. Fairhurst), Pottsville, "The Cyanide Process."

FOR THE DEGREE OF METALLURGICAL ENGINEER

Robert Fulton Crawford, Steubenville, Ohio, "A Study of the Thermal Efficiency of a Zinc Furnace."

Paul Robert Snyder (with C. C. Walters), Bethlehem, "The Influence of Various Paint Coatings on Radiation Losses From Furnaces."

Albert Poole Spooner, Harrisburg, "A Study of the Duplex Process of the Bethlehem Steel Company, South Bethlehem Pa."

Clarence Claitan Walters (with P. R. Snyder), Bethlehem, "The Influence of Various Paint Coatings on Radiation Losses From Furnaces."

FOR THE DEGREE OF ELECTROMETALLURGIST

Moses Appel, Baltimore, Md., "The Electrolysis of Copper Matte."

Joseph Ralph Dawson (with N. M. Downs), Washington, "The Physical Properties of Electroplated Alloys."

Nelson Miller Downs, E. M., Lehigh University (with J. R. Dawson), Steelton, "The Physical Properties of Electroplated Alloys."

Maurice Good, Havre de Grace, Md., "The Regeneration of Cyanide Solutions by the Use of Cyanamid."

Thomas Claude Kraemer, Pottsville, "A Proposed Method of Electrolytically Treating Speiss."

Claude Calvin Messinger, Allentown, "The Production of Ferro-Boron From Colemanite."

COST OF CYANIDE PROCESS

In 1894, the cost of treating Cripple Creek ores by the cyanide process was $15 a ton; in 1910 it was $1.50 a ton, with a prospect of a further reduction to $1.25 and $1 a ton. This has added very largely to the field for profitable ore reduction, not only in Cripple Creek but throughout Colorado.

DEVELOPING POVERTY GULCH CLAIMS

By Chas. W. Henderson

(Continued from June)

Plans for Development.—Plans are drawn for an inclined shaft to follow the intersection of the dikes in the foot-wall. All prospecting work has been stopped on the chutes *A* and *B*;* one hoist is to be used in sinking the inclined shaft, while one is to be used to take ore out of the prospect hole and to continue the exploration work.

Cost and Method of Sinking Shaft, Drifting, Constructing Underground Ore Bins, Etc.

It is assumed that by the time the inclined shaft has reached the first level drifts already excavated, the plans for the surface buildings will be finished and the cost determined, and that by the time the shaft has reached the second level the contract will be let for building the surface structures, and all mining equipment will be ordered. This gives 210 days for the erection of surface buildings and for machinery to arrive while drifts and raises are being driven.

The first consideration is the construction of a spur 5,010 feet long to the Colorado Springs & Cripple Creek District Railroad on a 4-per-cent. grade, with a switchback at the 3,400-foot station.

The cost per mile of this track is estimated as follows:

Grading, all earth excavation	$ 7,000.00
Ties, 2,112, at $1 (8½ feet long ×7×9, placed 2½ feet apart)	2,112.00
96 tons of 60 pound rails, at $58 delivered	5,568.00
9,244 spikes, 4,622 pounds, or 31 kegs of 150 pounds	150.00
Tracklaying	600.00
Joints, 352 per mile	300.00
Small wooden bridges	400.00
Per mile	$16,130.00
For 5,010 feet	$15,300.00

Preparations are next made to sink the shaft in the foot-wall about 50 feet below the ore at the intersection and at a distance of about 20 feet on either side from the ore extending along the two dikes. Conditions warrant sinking a shaft at an inclination of 22° 42′, as the work must necessarily be a series of steps of shafts and level, winze and level, etc., if carried on. This necessitates tramming to the foot of the winze, hoisting to the top of the winze, tramming to the shaft, and then out.

For development work, the 8-horsepower electric hoist and the prospecting head-frame on hand can be used. The size of a shaft to go down 1,000 feet on the incline and large enough to accommodate the handling of 200 tons of ore a day and to accommodate all future increase in tonnage, is 12 ft.×7.5 ft. in the clear. This sized shaft belongs in the middle class where it is about as cheap to put down a fair-sized shaft as to put down a small one, as a small shaft will allow for only a small number of workmen.

With the addition of a small compressor and air drills the equipment left from prospecting operations can be used, including the buckets and old shafts of the three prospects. The prospect head-frame, Fig. 1, is fitted with a simple automatic dumping device.

The shaft is timbered with the sets shown in Fig. 2, the track being laid full 33½-inch gauge for the skip.

When the shaft has been sunk a short distance, two skips are added to the equipment. These weigh 550 pounds, hold 10 cubic feet (930 pounds), and cost $60 each, with an addition of $10 for water valve.

With these skips it it proposed to hoist all the material broken in the drifts and to handle the small amount of water encountered. The 8-horsepower hoist handles the rock broken during sinking and drifting.

There are purchased also, 16 standard ore cars, capacity 14 cubic feet, fitted for 24-inch track gauge, No. 4 thickness of steel (¼ inch), weight 570 pounds, and price $45 each.

In using these cars before the ore pocket is built, the cars are loaded only enough to fill the skips.

* See Map, June Mines and Minerals, page 694.

Cost of Equipment

Six Little Giant drills, 2¼-inch diameter	$ 900.00
Six columns and arms up to 8 feet	240.00
Six sets drill steel, each 15.4 pounds, at $14.40	86.40
Buffalo exhaust fan, diameter outlet 24½ inches, price with bed and countershaft	700.00
460 feet of 24-inch pipe, at $54 per 100 feet	248.40
1,200 feet of 12-inch pipe, at $27 per 100 feet	324.00
Ten Leyner No. 5 stopers, $135	1,350.00
Drill steel, 10 sets, at $15	150.00
Sixteen ore cars, at $45	720.00
Compressor, motor and pipe, freight	2,689.14
Freight on 19,553 pounds, at $.55 per 100	107.54
Total	$7,515.48

In the development work two drills will be needed in shaft sinking and four drills in drifting. The drills are to be 2¼ inches in diameter and use air at 90 pounds pressure per square inch at drill. According to the catalog specifications, each drill will need 67.2 cubic feet of air per minute. The factor to determine a compressor capacity for four drills at 10,000 feet altitude is 4.49; hence, 301.5 cubic feet of air per minute will be required, but deducting 5 per cent. for leakage and allowing the compressor a volumetric efficiency of 80 per cent., the total air required is nearly 400 cubic feet per minute.

E. A. Rix allows 20 horsepower for every 100 cubic feet of cylinder displacement, to compress air to 90 or 95 pounds gauge pressure at sea level. Although 20 horsepower is higher than the value given by Peele for the theoretical horsepower required, and figuring efficiency the figures would then be below 20; but, since compressors are usually purchased for excess power to supply possible additional uses, and the use of 20 horsepower would only add a small percentage on the safe side, the power necessary for four drills is taken at 80 horsepower, and it is decided to purchase a two-stage air compressor 18″×11″ diameter, 12-inch stroke, 125 revolutions per minute, with a capacity of 440 cubic feet at 10,000 feet elevation.

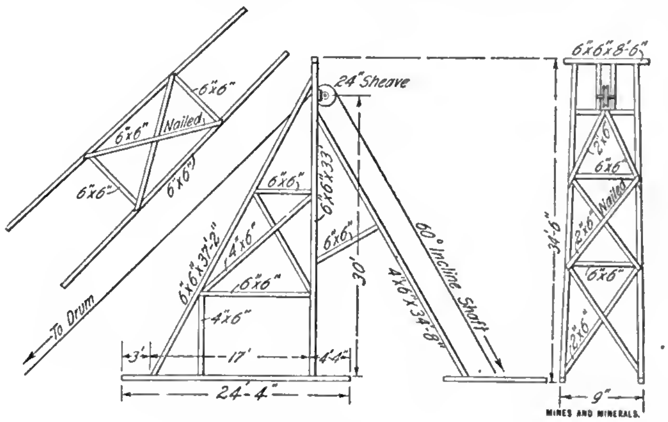

Fig. 1. Prospect Head Frame

This sized compressor gives a reserve of 21 per cent., and costs with freight from Denver to Cripple Creek $1,903. The motor for the compressor is 80 horsepower, 900 revolutions per minute, 440 volts, and costs delivered $710.84.

The following calculations give the power consumed during development by two piston drills: The catalog multiplier is 2.39 and as each drill will need 67.2 cubic feet of air, 67.2×2.39 = 159. Allowing for air loss in pipe line and efficiency of compressor, 210 cubic feet are necessary, or 42 horsepower per minute.

Each stope drill requires 25 cubic feet of air per minute and the factor for seven drills is 7.55; therefore, 25×7 = 189 cubic feet, to which 63 cubic feet is added to allow for loss and efficiency, and this is equivalent to 50.4 horsepower.

The power for two stope drills is 25×2.5 (multiplier) = 62.5 cubic feet of air, and if to this be added 20.7 cubic feet for pipe loss and efficiency, the power required is 16.68 horsepower. The diameter of the pipe needed for carrying air 800 feet is 3 inches and will cost at Cripple Creek $75.30. The total cost of compressor, motor, and pipe is $2,689.14.

Shaft Sinking.—The area of a 12′×7.5′ shaft is 90 square feet, and the arrangement and number of drills decided on is shown in Fig. 3. Each of the 18 holes will be 4 feet deep, and one man with a 2¼-inch diameter drill is capable of drilling 39 feet in 8 hours, or at the rate of 4⅞ feet per hour. If two drillers are put at work they can put in the 72 feet in 7.4 hours.

In this way an advance of 3 feet is made every round; blocking out 3×12×7.5=270 cubic feet of solid material, which is equivalent to $\frac{270}{12.4}=21.8$ tons broken each round, or

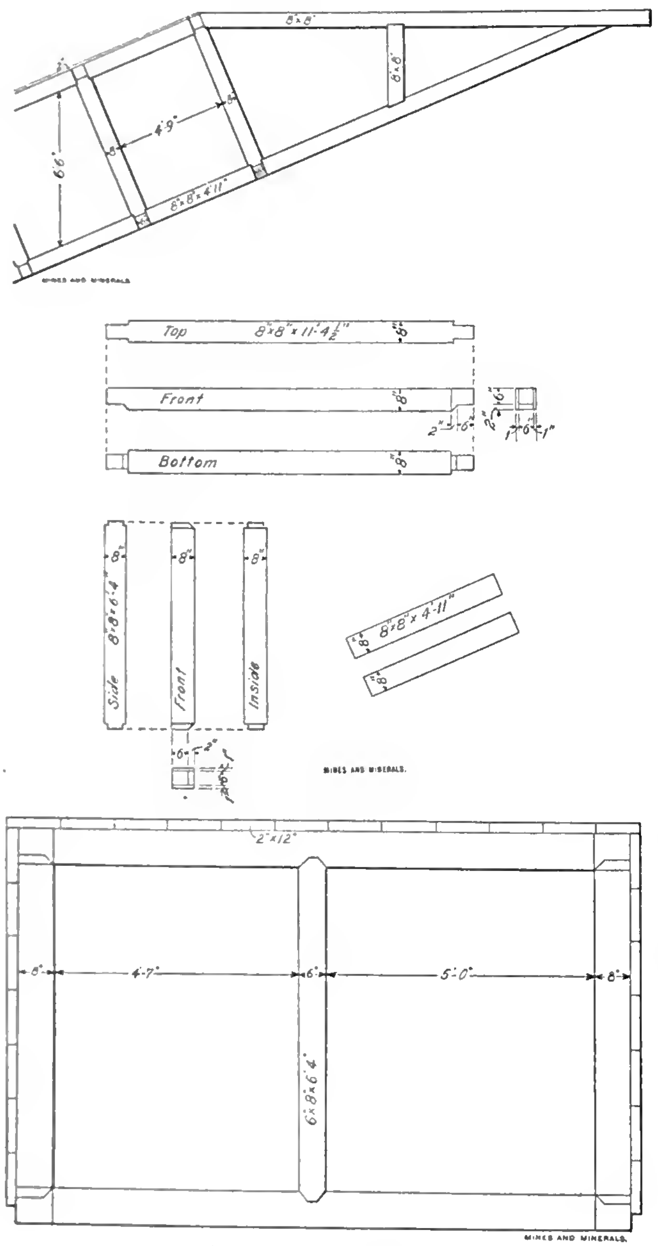

Fig. 2. Shaft Timbering

21.8×21.5 cubic feet=469 cubic feet,=17.4 cubic yards loose. To estimate the cost of handling the material: It will take two men $\frac{17.4}{2.4}=7\frac{1}{4}$ hours to muck out the rock broken in one round, and if ¾ hour be allowed for delays, changing skips, etc., one round can be drilled, fired, and removed every 16 hours. With this rate of progress the advance will be 90 feet per month.

To estimate the explosive required, take the depth of each hole at 4 feet, and assume that six sticks of 40-per-cent. dynamite, each weighing $\frac{6}{10}$ pound, or 3.6 pound per hole, are required; then 18 holes, per round, require 64.8 pounds of explosive.

The shaft is to be sunk 570 feet, a distance of 461 feet to reach the lowest workings, and then an allowance of 89 feet to provide room for underground ore bin to be made and 20 feet additional for a sump. The time required to sink the shaft will be

$$\frac{570}{3\text{ ft. per round}}=190\text{ rounds, or days.}$$

The detailed cost of sinking 570 feet of a 90-square foot inclined shaft is as follows:

Cost of Shaft Sinking

Two machine men, 190 shifts, at $4.50		$ 1,710.00
Two muckers (also top men) 190 shifts at $3		1,140.00
Two hoistmen, 190 shifts at $4.50		1,710.00
One blacksmith, 190 shifts at $4.50		855.00
One blacksmith helper, 190 shifts at $4		760.00
One foreman, 190 shifts at $4.50		855.00
One superintendent, at $175 per month, 6⅓ months		1,108.35
One timberman, 190 shifts, at $3.50		665.00
Powder, 12,312 pounds, at $.127*		1,563.62
Fuse, 190 rounds, 7-foot lengths, 23,940 feet, at $.0035*		83.79
Caps, 3,420, at $.007*		23.94
Depreciation on steel		14.40
Operation compressor plant (power), 336 horsepower hours per day:		
Installation charge	$ 20.50	
40,000 kilowatt hours, at $.013	520.00	
7,700 kilowatt hours, at $.005	38.50	579.00
Timber, 95,440 feet, at $20 per thousand		1,908.80
Electric power, for hoist, average 6.23 horsepower hours per hour, 49.84 horsepower hours per day, 9,470 kilowatt hours (190 days) at $.013		123.11
Coal for blacksmith, 28.75 tons, at $20.75		243.20
Candles, 950, at $.0145		13.78
Rails (30-pound), 570 feet, 5.08 tons, at $50		254.00
Cost for 570 feet		$14,207.55
Or cost per foot		$ 24.93

* These low costs of powder are those of the Portland Gold Mining Co. and include freight and unloading charges.

Cross-Cuts and Stations.—At vertical depths of 52 feet and 178 feet, two stations are to be cut the width of the shaft and 10 feet high in order to allow timbers, steel, etc., to be handled. The stations, Fig. 4, are made 14 feet long, 12 feet wide, and 10 feet high, narrowing at the cross-cuts to 7 feet wide, 7 feet high, and a length of 30.4 feet, at which point the mouth of the underground ore bin is reached. This demands a cross-cut at right angles to the cross-cut from the station, 13 feet wide, 7 feet high, and 17.25 feet long to connect with the drifts.

Underground Ore Bin.—A raise is to be started from the shaft to connect with the bin mouth and form an ore bin, Fig. 5. It is to have an average length of 20 feet, average width of 13 feet, and a height of 6 feet.

The two raises are to be made with Leyner No. 5 stopers. One drill is capable of making holes that when blasted will break 8 tons. As there are 20×13×6 =1,560 cubic feet, $\frac{1,560}{12.4}$=about 126 tons in an ore bin, and one man in each raise will break 8 tons, it will require $\frac{126}{8}$=about 16 shifts to drive one raise. This will produce 126×21.5=2,710 cubic feet, or 100 cubic yards broken material, and require $\frac{100}{1.1}=91$ hours, or 12 shifts, for one man to load into cars.

The bill of timber for the underground ore bin is as follows:

Number Pieces	Size	Board Feet
2	8″×12″×19′ 4″	320
2	8″×12″×15′ 8″	256
4	6″×12″× 5′ 9″	144
5	3″×12″×16′ 0″	240
11	3″×12″× 5′ 9″	198
5	2″×12″×11′ 0″	120
4	2″×12″× 5′ 0″	48
16	3″×12″× 9′ 0″	480
1	2″×12″×50′ 0″	100
7	3″×12″× 5′ 9″	126
2	8″× 8″× 7′ 0″	85⅓
2	8″×12″×12′ 0″	192
1	8″× 8″×10′ 10″	64
Total board feet		2,373⅓

The steel needed for an underground ore bin of the size specified is: Iron plate, 24 in. × 7 ft. × ¼ in. = 142.8 pounds; iron chute (total area) 4 ft. × 5 ft. × ¼ in. = 204 pounds; grizzlies, 5 ft. × 13 ft., space between bars, 3 inches, ⅝-inch rods, 65 square feet, 14 pounds per square foot, total, 910 pounds, at $1 per square foot.

The powder that will be consumed in raises for an underground ore bin is: 4 pounds powder per ton, or 504 pounds; fuse, 4 feet per ton, or 504 feet; caps, 1.4 per ton, or 177 caps.

The station, which is to be 14 feet long, will need 24 holes in the face, each 3 feet deep, in order to make an advance of 2 feet per round. Each hole will require four sticks of dynamite, or 2.4 pounds per hole, and 57.6 pounds per round.

One man can put in 39 feet of holes in 8 hours, or $4\frac{7}{8}$ feet per hour, and because there are 72 feet in each round it will take $\frac{72}{2\times 4\frac{7}{8}} = 7+$ hours, and with two men laboring per round, this station will take $\frac{14}{2} = 7$ rounds, or 7 shifts, and use up $7\times 57.6 = 403.2$ pounds of 40-per-cent. dynamite.

An estimate of the labor required is as follows: $10\times 10\times 14 = 1{,}400$ cubic feet of material broken, or $\frac{1{,}400}{12.4} = 113$ tons broken for the station. 113 tons × 21.5 = 2,430 cubic feet of loose rock, or 90 cubic yards, which will require $\frac{90}{1.1} = 82$ hours for one man to load in cars. Two men will load the material in 41 hours, or $5\frac{1}{8}$ shifts, or to tram the material will require $114\times 2\times 2 = 456$ minutes, about 8 hours, or one shift. The labor needed, therefore, will be seven shifts of two machine men, six shifts of two muckers.

The progress and powder on the proposed cross-cuts is estimated next; the dimensions of each cross-cut being 7 ft. × 7 ft. × 30.4 ft. Fifteen holes are needed in the face, each 3 feet 6 inches deep, to furnish an advance of 2.44 feet per round. Each hole will require 2.88 pounds dynamite, or

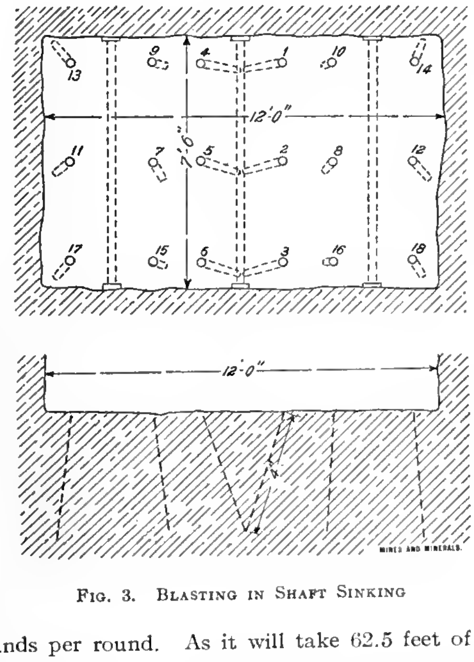

Fig. 3. Blasting in Shaft Sinking

43.2 pounds per round. As it will take 62.5 feet of holes for one round, the time occupied in drilling will be $62.5\times\frac{4}{39} = 6.4$, say 7 hours, and there will be $\frac{30.4}{2.44} = 12.45$ rounds.

In all it will take about 12 shifts to make this cross-cut, with 537.84 pounds of powder. The progress in the second cross-cut, whose dimensions are 13 ft. × 7 ft. × 17.25 ft., provided there are 24 holes in face, and 57.6 pounds powder per round, will be, when it takes 7 hours to put in one round, about $\frac{17.25}{2} = 8.63$ rounds, or 9 shifts. The nine rounds will consume 518.4 pounds of 40-per-cent. dynamite.

7 ft. × 7 ft. × 30.4 ft. = 1,489.60 cubic feet broken in first cross-cut. 13 ft. × 7 ft. × 7.25 ft. = 1,569.75 cubic feet broken in second cross-cut, or a total of 3,059.35 cubic feet broken in

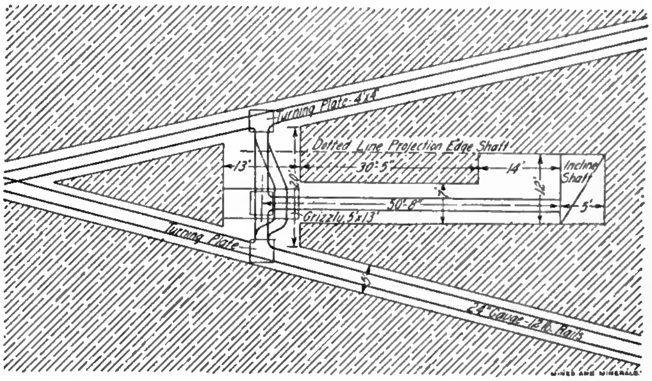

Fig. 4. Plan of Station

both cross-cuts, or $\frac{3{,}059.35}{12.4} = 247$ tons solid broken, which is equivalent to $247\times 21.5 = 5{,}310$ cubic feet, or 196.5 cubic yards of loose material, and it will take $\frac{196.5}{2.2} = 89.4$, say 90 hours, or about 12 shifts, for two men to load the broken material in cars, but there are 594 half-ton cars to be filled, and these, trammed at the rate of one every two minutes, takes up 1,188 minutes, or 20 hours, or the time of one man $2\frac{1}{2}$ shifts.

Cost of Cross-Cuts and Station

One superintendent, 14 days, at $175 per month	$ 81.66
One foreman, 14 days, at $4.50 per day	63.00
Two machine men, 28 shifts, at $4.50 per day	252.00
Two muckers, 28 shifts, at $3 per day	168.00
Powder, 1,459.24 (pounds), at $.127	185.32
Caps, 487, at $.007	3.41
Fuse, 1,461, at $.0035	5.11
Drills (depreciation)	.84
Candles, 616, at $.145	8.95
Rails, 85 feet, 12-pound rails, .327 gross ton, at $47	15.37
Thirty ties, 4 in. × 6 in. × 3 ft., at $.41 (freight, $3.30)	15.60
Turnplates, 4, at $18	72.00
One blacksmith, 14 days, at $4.50	63.00
One helper, 14 days, at $4	56.00
Coal for blacksmith, 5.6 tons, at $20.75	116.20
Freight, rails, etc. 733 lb. } 1,453 lb. at $65 per 100; Freight, 4 plates, 180 lb. each, 720 lb. }	9.44
Hoist (power for) 520 kilowatt hours, at $.013	6.76
Compressor power, 4,704 kilowatt hours, at $.005	23.52
Cost for about 68 feet	$1,146.18
Cost per foot about	$16.61
Cost of two stations and cross-cuts	$2,292.36

Cost of Underground Ore Bins

(Superintendent, foreman, and one blacksmith salaries included under Stations and Cross-Cuts.)

One machine man, 16 shifts, at $4.50	$ 72.00
One mucker, 12 shifts, at $3	36.00
Powder, 504 pounds, at $.127	64.00
Fuse, 504 feet, at $.0035	1.76
Caps, 177, at $.007	1.24
Compressor power, 133.36 horsepower hours per shift, total 1,590 kilowatt hours, at $.005	7.95
Hoisting power (included under stations)	
Candles, 112, at $.0145	1.62
Timber, 2,374 board feet, at $20 per thousand	47.48
Iron plate, 142.8 pounds } Iron chute, 204 pounds } at $.02¼	7.80
Grizzlies, 65 square feet, 14 (pounds) per square foot, $1 per square foot	65.00
Freight on iron, 1,256.8 (pounds), at $.65 per 100	8.17
	$313.02
Cost of two ore bins	$626.04

Drifts.—The work of drifting, if carried on by hand, will be hampered by bad air and the necessity of hoisting in two stages, but the advance will be about 800 feet on the 60-foot level. The stations have been cut at vertical depths of 52 feet and 178 feet, and cross-cuts run to connect with the hand-

drilled drifts. A compressor has been in use for the machine drills for shaft sinking for the stations and cross-cuts, and the drifts are now to be driven by machine drills.

The drifts are 7 ft. × 5 ft. in the clear, grade, ½ per cent.; rails, 12-pound; 24-inch gauge; ties, 4 in. × 6 ft., and placed on 3-foot centers.

The Portland Gold Mining Co. has decided that the small 2¼-inch hammer drills are decidedly better for cross-cutting and drifting.

The results obtained in working the property of the Portland company show that there is no ground in their property

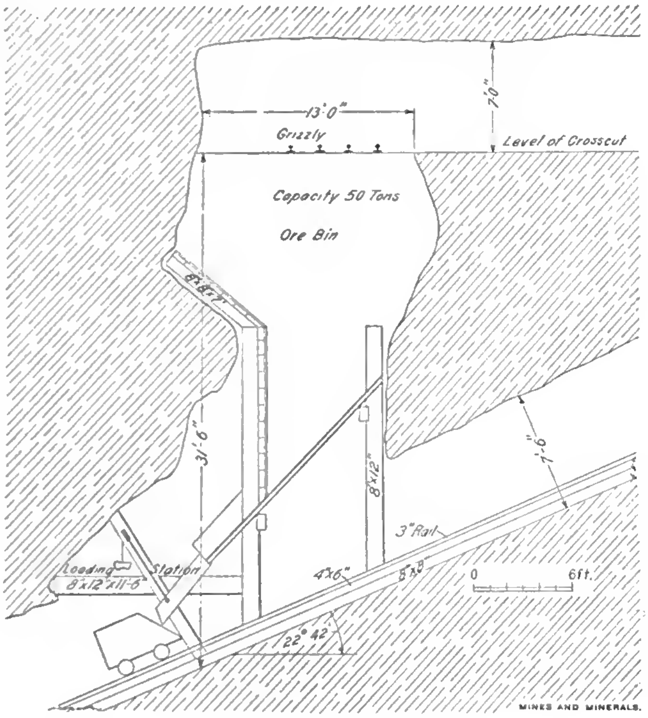

FIG. 5. UNDERGROUND ORE BIN

which cannot be handled with the small machine. During a period of 2 years there have been driven with them 4 miles and 308 feet of development headings, through a diversity of ground, including Pike's Peak granite (a coarsely porphyritic type of granite), highly indurated, andesitic, or phonolitic breccia; true massive andesite; trachitic phonolite; tufas; and along dikes of decomposed basalt and hard phonolite.

The method of driving drifts is shown in Fig. 6. As shown, nine holes are drilled in the face, each 3 feet 6 inches deep, and with these blasted an average advance of 2.44 feet per round is made. Each hole has an average charge of 4.8 sticks of 1¼"×8" dynamite, weighing $\frac{6}{10}$ pound per stick, or $9\times4.8\times.6=25.92$ pounds per advance of 2.44 feet.

One man can put in 39 feet of holes in 8 hours, or 4⅞ feet per hour; but as one man is required to drill only 31½ feet per round, it will take him $\frac{31.5}{\frac{39}{8}}=6\frac{1}{2}$ hours.

Aside from the usual work of loading and firing, the machine man helped the mucker to place flat steel plate 48×96×⅜ in. in place during 1¼ hours of his shift. The number of tons of material to be loaded and trammed to the shaft is found as follows: $\frac{7\times5\times2.44}{12.4}=\frac{85.4}{12.4}=6.89$ tons (solid), or 6.89×21.5 cubic feet = 148 cubic feet, or 5.5 cubic yards loose.

A man can shovel 1.4 yards from steel in 1 hour, and 5.5 cubic yards in say 4 hours.

The 600 feet of drifts are to be worked in four faces, each furnishing 6.89 tons of material per day, or 14 half-ton cars. When 56 cars are to be trammed per day at the rate of one every 4 minutes, it will take one man 3 hours and 44 minutes to tram all the cars.

Three muckers should be able to load and tram, lay the track, and load the skips in 8 hours.

Cost of Drifts.— 2.44 feet advance made in each heading per shift equals 9.76 feet in the four headings, which estimate places the time at $\frac{600}{9.76}=61.4$, say 62 shifts to run drifts.

One superintendent, at $175 per month, 31 days	$ 180.85
One day foreman, 62 shifts, at $4.50	279.00
One night foreman, 62 shifts, at $4.50	279.00
Four machine men, 62 shifts, at $4.50	1,116.00
Three muckers, 62 shifts, at $3	558.00
One hoistman, 62 shifts, at $4.50	279.00
One blacksmith, 62 shifts, at $4.50	279.00
One helper, 62 shifts, at $4	248.00
Powder, 248 rounds, 6,428.16 pounds, at $.127	816.38
Fuse, 2,232 holes, 3 feet, 6,696, at $.0035	23.44
Caps, 2,232, at $.007	15.64
Depreciation on steel	13.20
600 feet 12-pound rails and fastenings, 2.32 tons, at $47	109.04
200 ties, at $.41 each (plus freight, $21.12)	103.12
Cost of compressed air, 29,600 kilowatt hours, at $.005	148.00
Power for exhauster after firing (20 minutes a shift) 65 kilowatt hours, at $.005	.32
Candles, 936, at $.0145	13.57
Coal for blacksmith, 3.9 tons, at $20.75	80.93
Power for hoist, 2,300 kilowatt hours, at $.013	29.90
Freight on 4,640 (pounds) of rails and fastenings, at $.65 per 100	3.02
Cost for 600 feet	$4,575.41
Or cost per foot	$7.63

Including the two cutting-out subdrifts, there are three drifts worked at one time, making a total cost of $13,726.23.

The cost of driving the two subdrifts includes rails and ties, which are removed before stoping, and can be used elsewhere. There are, therefore, as an asset, rails and ties to the value of $212.16 for 1,200 feet of drifts.

Raises.—The five raises needed for manways and ventilation are put up from the second level (178.4 feet vertical depth); two are to be 139 feet long, and three are to be 155.5 feet. There are five raises to be put up from the first level (52 feet vertical depth); two of which are to be 39 feet long, and three are to be 48 feet long. These raises are to have a size of 4½ ft. × 6½ ft.

There are also twenty-four 6-foot raises to be driven for chutes, or 144 feet in all. The total length of the manways will be 966.5 feet, making a grand total, 1,110.5 feet. The quantity of material to be broken is $\frac{1,110.5\times4.5\times6.5}{12.4}=2,620$ tons, and because every stoper should break 8 tons per day the work

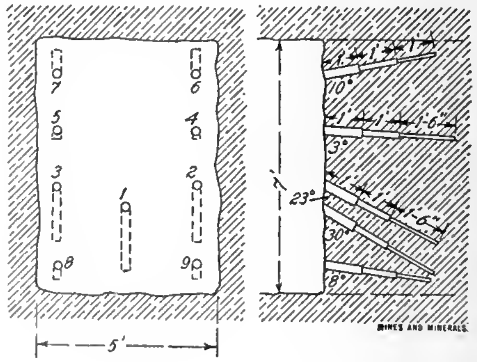

FIG. 6. BLASTING IN DRIFTS

should be accomplished in $\frac{2,620}{8}=327.5$ shifts. Seven men can work in these raises at one time without getting in each other's way, which gives an estimate of $\frac{327.5}{7}=$ about 47 shifts to a raise.

Cost of Raises

Powder, 10,480 pounds, at $.127	$1,320.96
Fuse, 10,720 feet, at $.0035	37.52
Caps, 3,700, at $.007	25.90
Seven machine men, 47 shifts, at $4.50	1,480.50
Two timbermen, 24 shifts, at $3.50	168.00
Timber	503.85
One superintendent, at $175 per month	140.00
Two foremen, 24 days, at $4.50	216.00
One hoistman, 47 shifts, at $4.50	211.00
One top man, 47 shifts, at $3	141.00
One mucker and skip tender, 47 shifts, at $3	141.00
One blacksmith, 24 shifts, at $4.50	108.00
One helper, 24 shifts, at $4	96.00
Power for hoist, 1,750 kilowatt hours, at $.013	22.75
Power for drills, 14,500 kilowatt hours, at $.005	72.50
Power for blower, 2,360 kilowatt hours, at $.005	11.80
Drills (depreciation)	12.50
Candles, 1,880, at $.0145	27.26
Cost for 1,110.5 feet	$4,747.04
Or cost per foot	$4.27

Lumber and Timber of Raises.—Stulls are placed in raises every 10 feet, with 10-foot ladders made of 2″ × 4″ lumber sides 14 inches apart, with nailed rungs 10 inches apart. There are needed 194 stulls 10 in. × 10 in., averaging 6 feet in length. As the length of the ladders will be 2,706 feet, there will be needed 1,624 strips 1 in. × 2 in., for rungs, each 18 inches long. Roughly, there will also be needed 388 pieces of 2″ × 6″ staging about 6½ feet long, and 24 chutes requiring 563 feet lumber.

Summary of Underground Costs (for Development and Time Expended)

	Days	
Additional equipment for development		$ 7,515.48
Shaft sinking	190	14,207.55
Cost two stations and cross-cuts to	14	2,292.36
Ore bins (underground), time included in above	14	626.04
Drifts and subdrifts	186	13,726.23
Raises	24	4,747.04
Total	414	$43,114.70

KATALLA, ALASKA, OIL FIELD

Written for Mines and Minerals, by W. T. Prosser

The oil fields of Katalla, Alaska, are attracting attention on the Pacific Coast, from the fact that the first large commercial shipment of this Katalla petroleum is promised shortly. Steel tanks to contain 37,000 barrels of oil have been shipped from Seattle to catch the flow of four producing wells. One tank from which vessels will load, will have a capacity of 30,000 barrels and will stand on Kanak Island, at the entrance to Controller Bay. Two other tanks, one of 2,000 and the other of 5,000 barrels, will be erected at the wells. A pipe line connecting the smaller tanks and the larger one, a distance of 8 miles, is almost in place, and will be ready before the reservoirs are completed.

Ten years ago, Dr. H. T. Burls, of London, England, made two trips to Alaska to collect data, and make observations and studies of the oil territory. Upon his report, which was supplemented by a very enthusiastic statement from Sir Boverton Redwood, his associate, work was begun drilling in the most favored locations. After oil was found, contending interests striving to gain possession of the most promising properties held up development for half a dozen years. It is only within the last year that new interests have gained possession, and are making ready to give the wells a chance to flow.

This new company found that the four old wells were choked with old iron and junk of all kinds, so that the oil could scarcely trickle out in drops. From one well two tons of debris were removed; then the flow carried away the top of the derrick, and settled down to a steady stream of about 720 barrels of petroleum a day.

Two of the other wells, in which the petroleum stood near the surface, were stimulated by the use of a pump, and after that flowed a very satisfactory stream. The four wells at a test made last December, in the presence of two officials of the Interior Department, yielded a total of 2,100 barrels a day.

Since that time they have been capped, awaiting the arrival and installation of equipment for taking care of the oil. The well with the greatest pressure creaks and groans at being held in restraint.

The oil belt is a strip of territory along the coast, averaging about four miles in width, and lying east of the Copper River's mouth. It is situated just to the southward of the Katalla coal measures, which so far as known are among the greatest in the world.

The Katalla oil is essentially a refining product, as it contains too high a percentage of valuable constituents to burn in its crude state. It is doubtful if there is another petroleum that can aggregate from 65 to 75 per cent. in gasoline, benzine, and kerosene. The Katalla oil averages about one-third gasoline and another third coal oil.

The following analysis of the oil is published by Prof. G. C. Martin, of the United States Geological Survey, in Bulletin 335, "The Geology and Mineral Resources of the Controller Bay Region, Alaska":

Distillation	Per Cent.
Below 150° C., naphtha	38.5
150 degrees to 285 degrees, illuminating petroleum	31.0
Above 285 degrees, lubricating petroleum	21.5
Residue, coke and loss	9.0

Katalla, Alaska

This same report shows that the Alaska oils have a percentage of gasoline 38.5, far higher than that of any other field on the continent. Pennsylvania is given as 16.5 per cent.; Ohio as 10; Colorado, 16; Mexico, 10; and Beaumont, Tex., as 2.5. The California oil is not included in this table, but analyses give it an extremely low proportion of gasoline—between the Texas and Mexican tests.

Gasoline-producing petroleum is not as plentiful as the demand, and almost the entire supply of the country comes from the Pennsylvania wells. Therefore the opening of the new Alaska wells will be appreciated by the consumers.

Doctor Burls and Sir Boverton Redwood expressed the opinion that it would not be necessary to go very deep in drilling for oil in the Katalla district, and their predictions were correct. The deepest producing well is 1,500 feet, and oil was struck in this well at a much higher level. Oil oozes out of the soil in so many places that the ground is saturated with it. Some of the seepages flow as much as two or three barrels a day. Part of the territory is low and marshy, penetrated by sloughs from the Gulf of Alaska, but equally as good indications and results have been obtained on the ground above.

Much operating will be done through the oil belt this year, and oil will win out against the Alaska coal in the race to get to the market.

RADIUM AND RADIOACTIVITY

By L. F. Miller, Professor of Physics, Colorado School of Mines

Different Rays and Their Effects—How to Recognize Radioactive Minerals

Radioactivity is a physical property exhibited only, so far as we know at present, by the elements uranium, thorium, radium, polonium, and actinium. They are called the radioactive elements. All excepting uranium, and thorium were unknown before the discovery of radioactivity. Like the discovery of the planet Uranus, radium, polonium, and actinium were first discovered through their effects instead of being observed directly.

Radioactivity is the property a substance has of sending forth a certain kind of invisible ray. There are a great many different kinds of rays projected by substances. Some emit a kind of ray which affects the nerves associated with the sense of touch, and are known as heat rays. Some send out rays which affect only the sense of sight; these are called light rays. Radioactive bodies send out a kind of rays which affect neither the sense of touch nor the sense of sight. They are invisible and can be detected only by certain physical effects which they produce. For instance, they may strike upon certain substances, as zinc sulphide or barium platinic cyanide and be converted into visible light rays. This is known as phosphorescence. They may be transformed into heat rays or produce certain chemical reactions, as when they fall upon a photographic plate, or finally they may pass into a non-conducting gas and make it conducting to electricity. This latter effect is called ionization. These rays also have the property of penetrating certain substances which ordinary light rays do not have. Some will pass through thick layers of iron and other metals with very little decrease in intensity.

Much was known about these rays, through the study of X rays, Crooke's tubes, and electric spark discharges, before the study of the radioactive elements. But they were never investigated as thoroughly as they have been since the discovery of the phenomena of radioactivity. Now it is found that these rays may be divided into three classes, according to the different physical properties which each exhibits. The three classes are designated by the three Greek letters, α alpha, β beta, and γ gamma. In general they all have penetrating power, but in varying degrees. They all have ionizing power, but the more penetration the rays have, the less effect they have as ionizers, that is, in making a gas conducting to electricity.

The alpha rays have very little penetration and are entirely absorbed by a sheet of aluminum one-tenth of a millimeter thick, or an ordinary thick sheet of paper, or even a few centimeters of air. They are the strongest ionizers, but they have very little photographic effect. If the rays are allowed to pass through a magnetic field they are bent from their path in such a way as to show that they are positively charged particles. The same effect is produced by an electric field.

The beta rays are more penetrating and require a five-millimeter thickness of aluminum to be completely absorbed. They have less ionizing power than the alpha rays, but the greatest photographic action. In an electric or magnetic field they are deflected much more readily than the alpha rays and in the opposite direction. This latter condition indicates that the beta rays are negatively charged particles.

The gamma rays are the most penetrating of all and will pass through 30 centimeters of iron or several centimeters of lead without much absorption. They have the least ionizing power and very little photographic action. They are not deflected in the least by either a magnetic or an electrical field. Therefore, they do not appear to carry an electric charge.

If r in Fig. 1 represents a small amount of radium at the bottom of a narrow tube, the three types of rays, alpha, beta, and gamma emitted by this radioactive substance when in a magnetic field may be illustrated as shown in this figure.

The beta rays are bent much more readily and opposite to the alpha rays, but the gamma rays remain undeflected.

Uranium, thorium, radium, and actinium emit all three classes of rays, but polonium gives off only the alpha rays. The relative proportions of rays given off are different for the different elements. For instance, the ionizing powers of thorium and uranium are about equal, so they must emit about the same proportion of alpha rays. But the photographic effect of thorium is much weaker than that of uranium. Therefore, the beta rays from the latter must be stronger than from the former. Poloninum shows practically no photographic effect or penetrating power at all, but its alpha rays produce strong ionization. The rays from actinium have about the same relative intensities as the rays from thorium, but they are all much stronger. Radium has the strongest rays of all, about 1,000,000 times more active than uranium.

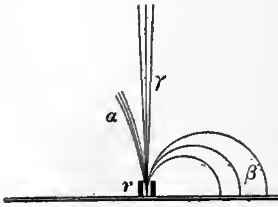

Fig. 1

It was found that by treating uranium by a certain chemical process a product could be dissolved off, which would give only the beta rays, while the product remaining behind showed now alpha rays but no beta rays. After a time this remaining product, which may be regarded as the original uranium, would begin to show beta rays again. Investigation revealed the fact that uranium is continually forming a product, by transformation, that may be removed chemically and gives only these beta rays, while the original uranium is the part that gives the alpha rays. After a time this original uranium forms more of this product by transformation and begins to show beta rays again. This transformation product, which can be separated from the original and which has been called uranium X, will finally exhaust all its beta rays and transform into another product of still different properties. Thorium and actinium have also shown the property of forming a similar transformation product which can be separated chemically as in the case of the uranium. A form of product similar to these has not been obtained from radium.

There is another form of emission given off by certain radioactive elements which is called an emanation. Investigation of all the previous products emitted by radioactive elements has shown that they are very minute particles, but these emanations which have been obtained show every indication of being a form of gas. Radium, thorium, and actinium give out these emanations, but, so far, uranium has not been found to give off any emanation. The strongest proof which we have that these emanations are of a gaseous nature is that it was not found possible to condense them on any object until they were cooled down to about $-150°$ C. by means of liquid air. This is one of the conditions for condensing a gas. These emanations will also diffuse through porous solids. These are not affected either by an electric or by a magnetic field, and although they seem thus not to consist of ions, yet they have the power of ionizing a gas and do not lose their power when they pass through cotton, wool, or when they bubble through solutions. They will also act upon a photographic plate.

It was also found possible to obtain transformation products from these emanations. That is, these emanations will transform into other emanations of still different properties. It is through the study of these various transformation products that we are brought upon the most startling discovery in the history of science. No credence has ever been put upon the alchemist's idea that one element can be transformed into another. But here in the phenomenon of radioactivity we seem to find such a process really taking place. For example, alpha particles obtained from uranium were collected, examined with a spectroscope and found to be helium, a substance which we have always regarded as an entirely different and separate element from uranium. From the

uranium X it was also found that, by transformation, radium was formed.

Uranium, originally, is not a composite substance as one might think from these results. In its primitive state before this transformation, it has properties which are entirely different and distinct from radium and helium. Their spectra are found to be entirely different when examined by a spectroscope, besides many other distinguishing properties. Polonium likewise originates from radium. The latest announcement is Boltwood's determination of another new element, ionium. Yet there are others still undetermined and some which exist for so short a time that they do not permit extensive investigation. Another evidence supporting this theory of a transformation process is that helium, radium, and polonium have never been found in nature except in association with uranium. Uranium and the other radioactive elements also exhibit another wonderful phenomenon in their continuous emission of energy in the form of heat, apparently without diminution and from the great difficulty is that radium is so rare that it is the most costly element on the market. What scientists are hoping to do is, by the study of this process of radioactivity in radium, to learn how a similar action may be brought about, regulated, and controlled in some cheaper form of substance. When this achievement has been accomplished we shall have at our disposal a greater store of energy than any form of supply known today. Radium has also won a very popular interest in medical practice. It was found to have a very powerful action upon animal tissues and was consequently hailed as a very potent factor in curing skin diseases and cancer. In light of all demand by the scientists and the medical profession, and because probably not more than half an ounce of radium has been produced in all the world, it is easy to understand why it should command such a high value.

Since radium has been found to be always a transformation product from uranium, it is natural to look for it only in those ores which contain uranium. The proportion of radium to the

Radioactive Minerals*

Name	Composition	Remarks
Uraninite	Oxides of uranium and lead	Occurs primary as a constituent of rocks and secondary in veins with metalliferous sulphides
Cleveite	Usually contains thorium and other rare earths and helium	
Broggerite		
Nivenite	Uranium 50—80%	
Pitchblende	Thorium 0—10%	
Gummite	$(Pb, Ca)\ U_3SiO_{12}\cdot 6H_2O$? Uranium 50—65%	An alteration product of uraninite. Formed by the action of percolating waters
Uranophane	$CaO\cdot 2UO_3\cdot 2SiO_2\cdot 6H_2O$	An alteration product of uraninite through gummite
Uranotil	Uranium 44—56%	
Carnotite	A vanadate of uranium and potassium Uranium 42—51%	Occurs as a secondary mineral impregnating a porous, sedimentary sandstone. Found in Colorado and Utah
Uranosphærite	$Bi_2O_3\cdot 2UO_3\cdot 3H_2O$ Uranium 41%	Alteration product of other uranium minerals
Torbernite	$CuO\cdot 2UO_3\cdot P_2O_5\cdot 8H_2O$	Alteration product of other uranium minerals
Cuprouranite	Uranium 44—51%	Alteration product of other uranium minerals
Autunite	$CaO\cdot 2UO_3\cdot P_2O_5\cdot 8H_2O$	Alteration product of other uranium minerals
Calciouranite	Uranium 45—51%	Alteration product of other uranium minerals
Uranocircite	$BaO\ 2UO_3\cdot P_2O_5\cdot 8H_2O$ Uranium 46%	Alteration product of other uranium minerals
Phosphuranylite	$3UO_3\cdot P_2O_5\cdot 6H_2O$ Uranium 58—64%	Alteration product of other uranium minerals
Zunerite	$CuO\cdot 2UO_3\cdot As_2O_5\cdot 8H_2O$ Uranium 46%	Alteration product of other uranium minerals
Uranospinite	$CaO\cdot 2UO_3\cdot As_2O_5\cdot 8H_2O$ Uranium 49%	Alteration product of other uranium minerals
Walpurgite	$5Bi_2O_3\cdot 3UO_3\cdot As_2O_5\cdot 12H_2O$ Uranium 16%	Alteration product of other uranium minerals
Thorogummite	$UO_3\cdot 3ThO_2\cdot 3SiO_2\cdot 6H_2O$? Uranium 41%	A variety of gummite
Thorite	$ThSiO_4$	A primary constituent of pegmatite dikes
Orangite	Uranium 1—10%	
Uranothorite	Thorium oxide 48—71%	
Thoriante	Oxide of thorium, uranium, the rare earths and lead. Contains a relatively large proportion of helium Uranium 9—10% Thorium oxide 73—77%	Occurs as a primary constituent of a pegmatite dike in Ceylon. Geological age probably Archean
Samarskite	Niobate and tantalate of rare earths Uranium 8—10%	Primary constituent of pegmatite dikes
Fergusonite	Metaniobate and tantalate of rare earths Uranium 1—6%	Primary constituent of pegmatite dikes
Euxenite	Niobate and titanate of rare earths Uranium 3—10%	Primary constituent of pegmatite dikes
Monazite	Phosphate of the rare earths, chiefly cerium Uranium .3—.4%	Primary constituent of pegmatite dikes

* Rutherford, Radioactivity, page 557.

no source except themselves. For example, it is found that one-half a grain of radium bromide gives out heat at the rate of two calories per hour, and in four years it yields 70,000 calories, and yet, in that time, no diminution in weight can be detected. It is difficult to estimate what will be the ultimate limit. All this energy arises from the disintegration of these minute particles which compose the atoms. Seventy thousand calories is enough heat to raise more than one pint of water from 0° to 100° C. If one-half a grain of coal is completely combusted, and this is the ultimate limit for this substance, it will give only 250 calories. Of course in the case of the coal it is an atomic reaction, while in the case of the radium it is a disintegration of the still smaller units of which an atom is now found to be composed. But it shows how immensely greater is the heat of combination of these small ions forming the atoms than the heat of combination of the atoms. Where one might conceive, then, how two or three grains of radium would furnish sufficient energy to run the Lusitania across the Atlantic, yet amount of uranium in an ore is so definite that Rutherford and Boltwood have determined the numerical relation. They found that there is .0000038 gram of radium to one gram of uranium. Thus one ton (2,000 pounds) would contain .0034 gram of radium for every percentage of uranium present. Or one ton of 60 per cent. uranium ore will contain two-tenths of a gram of radium, which is equivalent to .35 gram of pure radium bromide. Because of this extremely small portion of radium, it would require an ore with a considerable percentage of uranium to be worth treating for the extraction of the radium. This is why pitchblende has been used in preference to other minerals. As seen from the above list of various minerals containing uranium, pitchblende has the largest percentage. Of course some consideration must always be taken of the quantity of ore available. Thus carnotite, even though it has a smaller percentage of uranium, might be, in some cases, considered for extraction.

On the market, radium is found only as a salt—bromide,

chloride, or sulphate. What is generally spoken of as pure radium is merely the pure radium salt, usually the bromide. The best pitchblende is said to be obtained from Johangeorgenstadt, Saxony. If the radioactivity intensity of the sample from this locality is denoted by the number 8.3, the pitchblende from the Joachimsthal mine, Bohemia, has a value of about 7. However, the latter has the greater supply and so far has produced the greatest amount of radium. Pitchblende has also been found in Cornwall, but of a much lower grade, probably not much higher than 1.6. It has been made commercial, principally through the simpler and cheaper chemical methods of Sir William Ramsay for extracting the radium. Very good qualities of pitchblende, mostly in small quantities though, have also been obtained in the United States, in Connecticut, North Carolina, South Carolina, Texas, South Dakota and Colorado. In Colorado the pitchblende deposits have come from the Kirk, German, Belcher, Woods, and Alps mines, of Gilpin County. It is claimed that some of this pitchblende has run higher in its uranium content than any of the European products, and considerable has been shipped abroad. Several good carnotite deposits have also been found in Montrose, San Miguel, and Routt counties, Colo.

How to Recognize Pitchblende.—It occurs in fissure veins, in igneous rock like granite, and is valued for its uranium and radium contents. It is not found in sedimentary rocks like sandstone, although alteration products of it may be found therein. Such alteration products are colored yellow or greenish and, when in sufficient concentration and quantity, are valuable for their uranium contents. These deposits constitute the carnotite ore. The radium value in these is small, as a rule.

Pitchblende is found in vein matter in stringers varying from knifeblade thickness to several inches. It is "bunchy." The associated minerals in addition to vein matter are sulphides, such as zinc blende, galena, and iron pyrite. The latter usually predominates. Pitchblende is detected in these streaks by the following properties:

Color.—Pitch black, velvety black, brownish sometimes with a grayish or greenish cast. The streak on rough porcelain; i. e., the edge of a broken plate, is brownish black, olive green, or grayish.

Luster.—Dull, metallic, greasy, pitch like.

Fracture.—Conchoidal, that is, with smooth curved surfaces, to uneven. Brittle.

Hardness.—Less than quartz, about 5 or 6.

Specific Gravity.—Heavier than iron or steel, about 8 to 9.7.

Fig. 2

A hardness of about 5 or 6 is a little too hard to be scratched by a good knife blade and not quite hard enough to scratch glass.

Specific Gravity Test For Pitchblende.—A simple test for the specific gravity of the sample may be made if an analytical balance is at hand. Take a specimen about the size of an inch cube and weigh it. Then support over the pan of the balance a glass of water on a small bench, as shown in Fig. 2, so that the pan is still free to swing. The pan must not touch or rub against the bench or glass in any place. From the stirrup above the glass, support the sample with a fine thread so that it is totally immersed in the water. This immersion lightens the weight of the sample. Weigh the sample, subtract this weight from the first and divide the first weight by this remainder. This gives the specific gravity, which should be from 8 to 9.7.

Photographic Test For Pitchblende.—Since uranium and radium both emit pentrating rays which will affect a photographic plate, it is very easy to perform this test. Enclose tightly in a black heavy paper, so as to keep out the light, a photographic plate, noting first which is the film side of the plate. Lay the covered plate down with film side up and place upon it a key or some small flat metal object. Then lay the sample of ore upon the key. Place the whole in a drawer or away in the dark, because some daylight can leak slowly through

Fig. 3

the paper and affect the plate. After it has remained in this position for three days, develop the plate and find if an image of the metal object is obtained similar to that in Fig. 3. In that case the sample may be worthy of a laboratory test.

SOCIETY MEETINGS

The annual meeting of the Appalachian Engineering Association was held at Pottsville, Pa., June 2 and 3. A number of prominent engineers from the eastern middle and eastern southern states were present. Mr. Frank Hill, of Pottsville, Pa., who was on the entertainment committee, took charge of the visitors, some of whom were his friends and acquaintances when he was located at Roanoke, Va. At the morning session, papers were read by D. C. Weller, C. E., of Waynesboro, Pa., on "Hindrances to Municipal Improvements," and by E. B. Wilson, C. E., Scranton, Pa., on "Pillar and Room Mining," special reference being made to the proportioning of mine pillars. Dr. I. C. White, H. M. Payne, and E. A. Schubert took part in the discussion. Frank Hill, some time on the Pennsylvania Second Geological Survey, talked on the geology of the Schuylkill coal field and illustrated his talk by means of excellent maps that showed the folding of the coal strata. After lunch the visitors were shown through the Philadelphia & Reading Coal and Iron shops by Mr. Wood and his assistants and then taken by trolley to Tumbling Run to dinner.

At the business meeting in the evening the announcement was made that the officers elected for the following year were E. A. Schubert, Roanoke, Va., president; S. C. Weller, Waynesboro, Pa, vice-president; Henry M. Payne, Morgantown, W. Va., secretary; C. E. Krebs, Charleston, W. Va., treasurer. After the meeting there was a smoker at the Pottsville Club, where the visitors were entertained by Mr. Richards, General Manager of the Philadelphia & Reading Coal and Iron Co., Judge Coke, Reese Tasker, and other prominent men of Pottsville. Saturday an automobile trip was made to the Gilberton stripping, where Frank P. Weiser, division engineer, appeared; and next to the St. Nicholas colliery, where John H. Pollard, division superintendent met the party. From this mine a hurried trip was made to Ashland for lunch, and from that town to Pine Knot colliery, where Reese Tasker, General Superintendent Philadelphia & Reading Coal and Iron Co., met the party and accompanied them to Pottsville. The Appalachian Engineering Association consider that this meeting was the best they have had, and to those citizens of Pottsville who so lavishly entertained them they expressed their appreciation through Dr. I. C. White.

THE CRESSON MINE

Written for Mines and Minerals, by R. L. Herrick

Ranking fourth* in the list of the great producers of the Cripple Creek district stands the Cresson mine. Located on Raven Hill, about a mile north of the well-known Elkton mine, for lack of pretentious surface equipment, as shown in Fig. 1, the casual visitor might well be excused for classing the Cresson with the many neighboring properties of minor importance.

Method of Mining.
Hoisting Devices.
Boiler Pressure Regulator.
Electric Ore Cars.
Reports

Outside of the district the mine is little known, as it is owned by a close corporation of Chicago and Detroit men.

Not till 1906 did the mine pass the prospect stage and only since 1907, when its great ore bodies were found, has its production forced the recognition that it belongs in the first rank. The highest grade ore was mined on the upper levels, but the grade has decreased with depth, till now the ore shipped is considerably below the average for this district. During the year 1909 a total of 65,856 tons of ore was hoisted, of which 32,286 tons of sorted material was shipped.

The margin of profit in the gross production will probably compare with that at the three mines ranking above it in total production, and this in spite of a lower average grade of ore shipped. The average total cost of mining, figured on the basis of tons shipped, is said to be $5.02 per ton, which compares well with costs common in the district ranging from $7 to $12 per ton.† This cost of $5.02 per ton is obtained by adding the total expense chargeable to the mining operations, including management, and dividing by the total tons shipped.

Fig. 1. Surface Plant at Cresson Mine

Such a low cost in a district of rather uniformly high costs is to be explained first by the kind of ore bodies, and second by the economies effected in operation. The explanation of the latter is the main purpose of the following article.

The Cresson ore bodies are in granite invariably associated with and penetrated by a number of basic dikes. The ore may follow closely along the strike of the dike and be in contact with it, or in the well-defined sheeted zone closely following the dike. Again the ore may occur as an irregular body replacing the granite adjacent to the dike at a point where a series of fissures have evidently provided suitable physical conditions for metasomatic replacement.

The important ore bodies of the Cresson mine so far have been largely of the second type. One of the first ore bodies struck was the largest thus far exploited. It was encountered on the 600-foot level where its horizontal extent proved to be 60 ft. × 120 ft. Its vertical extent was from 80 feet above the 600-foot level down to the 800-foot level, a total distance of 280 feet. Another ore body on the 600-foot level had a shape like a long inverted radish with its main axis inclined about 70 degrees from the horizontal, its top resting just below the 600-foot level, and its tapering root extending to just above the 300-foot level. Its vertical extent was thus about 320 feet, and on each level its horizontal section was roughly oval. On the 600-foot level it was oval, 40 ft. × 70 ft.; on the 500-foot level, oval 45 ft. × 60 ft.; on the 400-foot level, roughly circular 60 feet in diameter; on the 300-foot level, oval 15 ft. × 40 ft.; and above this rounding out rapidly to a point. This particular ore body is well entitled to the name "chimney." Still another ore body which was being exploited at the time this article was written had a width varying from 12 to 30 feet on the 1,000-foot level and widening out to a fairly uniform width of about 30 feet in the stope above. Its length on the strike slightly exceeded 100 feet, and its vertical height had not been determined.

In each of these bodies the ore is calaverite, a telluride containing gold accompanied by minor quantities of pyrite. Owing to its degree of oxidation, however, the ore may be divided into three classes. The first class embraces ore mainly mined between the 200- and 400-foot levels, but in the case of one ore body it goes down to the 600-foot level. This ore is apparently a more or less complete replacement of the granite. It is soft and friable in spots, but mainly remarkable for its quantities of iron-stained clay which is probably the decomposition product of the granite feldspar. The second class of ore is somewhat similar to the first in that it is oxidized and iron stained, but carries only minor quantities of clay. This ore mainly goes down to the 800-foot level. The third-class ore, not necessarily of much lower grade than the other two classes, is mined mainly on the 900- and 1,000-foot levels. It is a hard, unaltered gray breccia of granite and basalt from the adjacent dike. Owing to the soft friable nature of the oxidized ore embraced in the first two classes mentioned and to the large size of the ore bodies, the cost of breaking ground is low. Indeed it has been nothing uncommon to break between 200 and 300 cars of ore in one round of shots. The method of mining followed is that of "filled stope" or "shrinkage stoping," and it was adopted to reduce the quantity of mine timber. This is accomplished by allowing a portion of the broken ore to accumulate in the stopes as a support for the walls and to afford a footing for the miners to work on. This method takes advantage of the fact that broken ore requires from 20 to 40 per cent. more space than does the solid ore; consequently, only enough of the ore broken each shift is drawn out to afford working room for the miners next the ore back.

In the Cresson mine about 100 cubic feet of solid rock occupies 125 cubic feet when broken, so that about 30 to 35 per cent. of the rock broken each shift is drawn off.

The method of exploiting an ore body is about as follows: If, as is usually the case, the ore body is in contact with a basalt dike, a drift is driven in ore along the wall constituted by the dike till the length of the deposit has been determined. One or two cross-cuts driven in ore to the other wall then give a good idea of the vagaries in width and also allow a more complete sampling of the ore. Upon the width and grade of ore largely depends the method adopted of supporting the weight of the stope to be mined above. If the ore is uniformly narrow, say 6 to 10 feet, and the grade rather low, a back of ore, whose thickness will equal that of the width of ore body, may be left to support the stope. If the width of ore body varies from about 10 to 30 feet or more, and assays an ounce or more of gold, both of which conditions usually exist together in the Cresson mine, the plan of leaving an ore back for support is quickly abandoned.

The ore on the floor level is then stoped out completely from wall to wall for a height of about 10 feet. The horizontal dimensions of the ore body now largely determine whether the stope shall be supported by stulls and lagging, or by square sets—the latter either open or filled. The size of most of the ore bodies permits the support of the stope on lagged stulls. If the width does not exceed the length of timber obtainable, say 16 feet,

* Professional Paper No. 54, United States Geological Survey. Probable order of ranking is: 1. The Portland; 2. The Golden Cycle; 3. The Vindicator; 4. The Cresson.

† The average cost at the Portland is given by Finlay in his "Cost of Mining" as $9.36 per ton shipped. This is probably a little high for present conditions.

the stulls are placed on a slant set in hitches cut on the foot-wall. If the width exceeds the length of timber, say 30 feet, two heavy timbers, from 14 to 16 inches in diameter, are spliced, that is cut half through and given a lap of about 2 feet. These spliced stulls are set horizontally, instead of inclined, and are supported from the level floor by posts 9 feet high, spaced from 6 to 8 feet apart. Such stulls have been found to provide ample strength and are both quicker placed and cheaper than square sets. In one case, however, a single run of filled square sets was used to support the excessive weight of an unusually large stope.

Having provided a floor for the broken ore, in which chutes are placed at about 15-foot intervals, the stope is carried up by the usual series of benches. At each end of the stope a manway is cribbed up and its top kept just above the level of the broken ore. The manway cribs are about 6 feet square and built up of 6-inch diameter round timber with the ends squared for about a foot in order to afford a spiking surface. The manway crib has a partition dividing it into a ladderway and chute. The latter is plank lined and ends in an ore pocket at the bottom. The ladderway contains 15-foot ladders, staggered, also the air pipes and a wooden box made of old slabs down which the dulled steel is dropped, thus protecting the ladders.

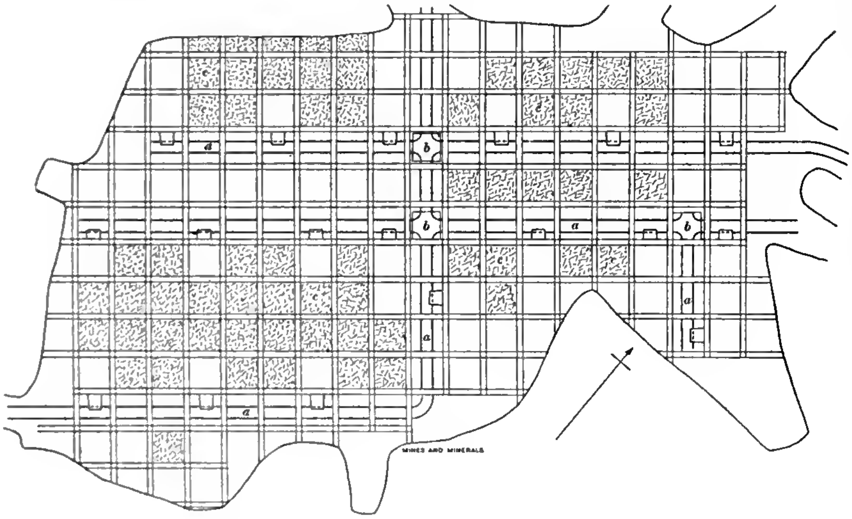

Fig. 2. Plan

After the stull lagging has been covered all over with a protecting layer of broken ore, a $4' \times 4'$ raise is started in the middle of the stope and driven to the level above. This raise is untimbered save for the few stulls necessary to support the ladders. It serves to ventilate the stope during its breaking upward and to bring down more air pipes. It is likewise used by the miners for descent into the stope when the climb up the manways from below has become more than 40 feet. With the exception of the drifts, which are usually driven by water Leyner drills, all stoping and raise driving is performed with the efficient little hammer drill of the Waugh type. By keeping the broken ore within working distance of the back, the series of benches are advanced wholly by the upper holes drilled. In a hard ground stope 100 feet long, six of these Waugh stope drills are usually worked to put in holes 4 feet deep.

The drill weighs but 62 pounds, and so can be rapidly moved about the stope by the drill runner. An average drill runner will drill from five to six 4-foot holes per day, although as high as 32 feet of hole per hour has been maintained in hard ground during periods of competition between drill manufacturers.

In the soft ground of the Cresson mine, as high as 10 holes per hour have been drilled In blasting the stope ore, 35 per cent. dynamite is used, about two sticks per hole being the common charge. In the soft ore of the Cresson mine two drill runners on one shift can commonly drill and shoot at least 200 tons of ore, an amount considerably in excess of the ordinary mining in the hard-ground stopes. An ore body is commonly exploited from two or more levels simultaneously. The uppermost stope is, of course, emptied of its accumulated ore first, a back varying in thickness from 8 to 30 feet being left between the top of the stope beneath and the floor level on which the ore is being drawn off. This thickness of overhead ore is varied to conform with the stope width and the strength of the ore. Eight feet suffices for hard ground of ordinary width, while 30 feet is none too much for the soft Cresson ground where the width equals or exceeds 30 feet. Having emptied the uppermost stope, the stulls may be left in or not, depending on the stope width.

In the large stopes of the Cresson mine, the timber is usually pulled out, the ore back filled with holes and shot down into the broken ore of the stope below, after which the next lower stope may be likewise emptied, and so on down. As long as the ore breaks fine enough to pass through the chutes, there is no trouble, but care has to be taken to avoid their choking with boulders.

After each shift shoots, a runner goes into each stope equipped with a light Hardscogg buzzer drill, searches out the boulders, and block-holes and shoots them into small pieces.

With this general description of a method which varies but little if any from the well-known practice, a few details concerning the exploiting of two stopes in an unusual manner may be of interest.

The first of these stopes has been previously stated to be about 60 ft. $\times$ 120 ft. in plan and 280 feet high. Having blocked it out on the 600-foot level, a single run or layer of square sets with posts 8 feet in the clear set on 5-foot centers was lagged over as usual. On account of the size of this ore body, four cribbed manways were carried up with this stope, each placed approximately in the middle of the four sides.

Fig. 2 shows in plan the arrangement of the 19 ore chutes (two more not shown were used) and the square sets. The car tracks *a* were arranged with turn sheets *b* placed at convenient intervals. After carrying up the stope some distance the weight of the broken ore became excessive, so that it was decided to fill enough of the sets to support the strain. In the illustration *c* represents those sets that were filled, the method being as follows: The groups of sets selected for filling were lagged inside after which the overhead lagging was shot down at enough points to allow the broken rock overhead to run in and completely fill the lagged space, which then acted as pillars to help support the strain. It will be noted that care was taken to leave a square set open either in front or behind each chute to allow ready access to it. This same scheme of work was followed on both the 700- and 800-foot levels below. After drawing the broken ore of the stope from the chutes and shoveling from the filled sets, the timbers were recovered by starting at one end and taking them back, retreating to the other end, taking up the tracks, etc. in the same order. It now remained to break down the back between the two stopes. Of course, this might have been drilled with holes from below and all shot down at once, but in the way actually followed the back was satisfactorily broken up with a considerable economy of labor and explosive over what the usual method would have involved. As fast as the top of the stope was brought up to within say 8 feet of the floor above, the back was immediately supported from the top of the broken ore by means of cribs built beneath the back and wedged against it. The cribs

were in some cases filled with broken ore. They were built similarly to the manway cribs and spaced on about 10-foot centers.

After having cribbed the entire back, its breaking was started as follows: A crib in the center of the back was selected as a starting point, and around this crib the drill holes were placed. The crib was then removed and the holes shot, breaking through a hole some 12 feet in diameter into the open stope above. After an interval of several days allowed for the rock thus loosened to work and drop, the back was again attacked adjacent to this center hole in a similar manner, drilling the holes in the protection of the crib and firing them after its removal. After the center hole had attained a diameter of about 30 feet, the bending of the whole back above resulted in giving it a slight saucer shape, bringing all the weight to bear on the cribs, and resulting in not only considerable incipient fracturing, but in rock strains which found relief in cracking when the blasting allowed further sagging. In this way the weight of the ore back was used to assist in its breaking down, thus reducing the amount of explosive. The primary object of the cribs, it is to be understood, was to protect the drill men while at work.

Having formed the central hole, the drill men were started at one end of the stope where a line of four cribs across the width of the stope supported the back. The back around the sides of each of these cribs was then drilled with holes, the cribs removed, and the back shot down the width of the stope. An interval of several days was then allowed for the stope to work, after which an adjacent strip of back was shot down in a similar manner. In this way the connection between the stopes was enlarged slowly, the cribs drawn line after line; in retreating toward the protected end of the stope, the men were always protected from working under a dangerously high roof, and the leaving of boulders too large to run through the chutes was avoided.

That the method is safe is sufficiently indicated by the fact that only one life was lost in the first 5 years' history of the mine.

With one exception, the ore deposits of the Cresson mine have been mined from two or more levels simultaneously. In the one exception, the ore body was stoped up about 320 feet from the 600-foot level in one great stope. This was the ore body whose shape was likened to that of an inverted radish, and whose western wall was formed by a basalt dike striking about N 30° E and dipping southeast about 70 degrees from the horizontal. Having been encountered on the 600-foot level, where the ore tapered down to a comparatively narrow streak, having its main axis along the basalt which formed a footwall, a drift was run along the basalt. Having left a back of ore above the drift about 10 feet thick pierced with chutes at 15-foot intervals, the stope was started in the customary manner. At the level of the top of the back, the ore widened out to 40 feet, but as the back was mainly country rock it was not taken out and the stope supported by timbers as in other cases. On approaching the 500-foot level, the softness of the ore and its excessive width would have necessitated the leaving of a 30-foot back below it for support. Instead of leaving this back and supporting the stope above on square sets, it was decided to carry the stope on up as before so that eventually it was carried some 10 to 15 feet above the 300 level. On the levels above the 600, however, the mine workings were extended to approach the ore body from the foot-wall side. Leaving the basalt as a barrier between the stope and the drift in the granite, chutes were driven through into the stope. From these chutes on the various levels the broken ore was drawn from time to time. Eventually, after the entire stope was completed, the ore was drawn simultaneously through the chutes on the various levels as well as from those on the 600. In this way the entire ore body was mined without the use of a stick of timber for supports, and the only timber used was that employed in the construction of manway cribs, and ore chutes.

Development Work.—The mine drifts are driven by contract. The No. 7 water Leyner drill, weighing 120 pounds, known as "the one man" drill, is used in this work. The contract usually stipulates the payment of $3 per running foot of advancement, on which basis the company furnishes the drill, air, and attends to repairs, while the drill runner furnishes his own powder and pays his trammer

Sinking is likewise done by contract, with conditions similar to those in drifting. The shaft timbers are placed by timbermen on company time. The lowest mine level is the 1,100-foot, from which sinking to the 1,200-foot is in progress. The shaft is vertical, having two compartments, each 4 ft. × 4 ft. in the clear. In the sinking work, the hoisting is done in the

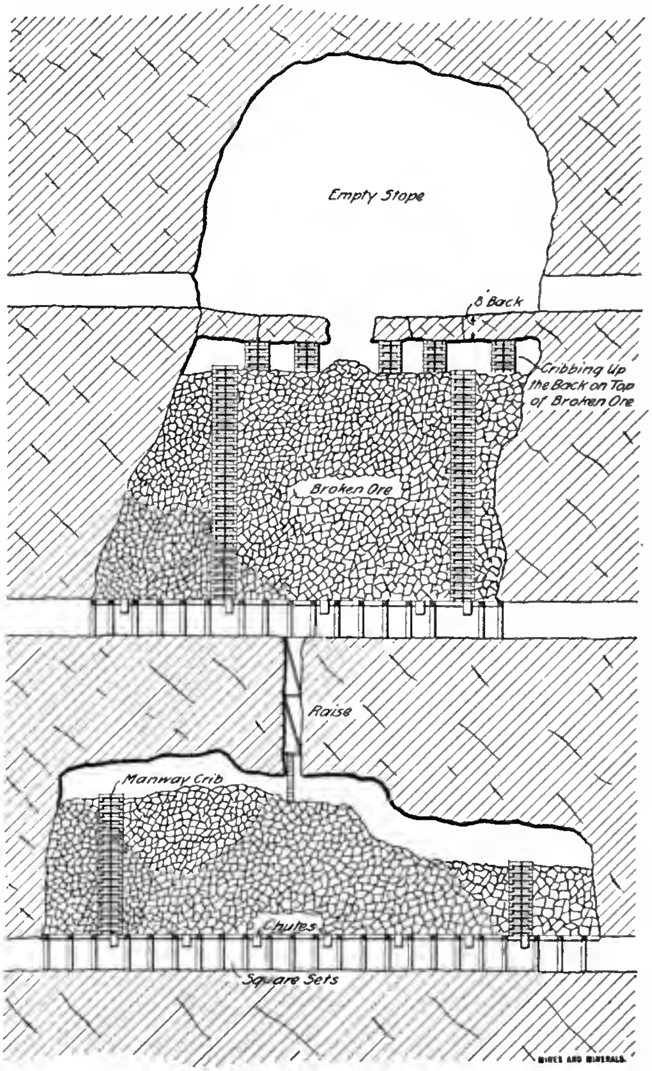

FIG. 3

manway compartment, the skipway being bulkheaded below the 1,000-foot for the protection of the men.

The sinking skip is run by a small compressed air engine located in the 1,000-foot station. On this level two swinging doors, one 4 feet above the other, protect the men below. By means of the well-known ball-and-chain device, these doors are opened as the skip comes up and closed behind it, before dumping, by means of two compressed-air pistons suitably connected to the doors by wire ropes. The air pipes connecting with these pistons run to within easy reach of the hoistman in the 1,000-foot station, who controls the piston movements by means of the usual valves. After dumping the skip into a car placed for the purpose, a movement of the valves causes the pistons to raise the shaft doors, after which the skip descends and the

pistons allow the doors to close after it. By means of these pistons, operated by the hoistman, the necessity of a top man at this point is eliminated, thus effecting a daily saving of his wages.

Drifting on the 600 level along a basalt dike, the emanation of carbon dioxide CO_2 gas from the rock interstices caused considerable trouble. Near the breast of the drift where the mine ventilation was naturally weak, an ingenious device was installed in order to prevent the CO_2 gas from entering this end portion of the drift, and measures to increase the atmospheric pressure at this point were taken as follows:

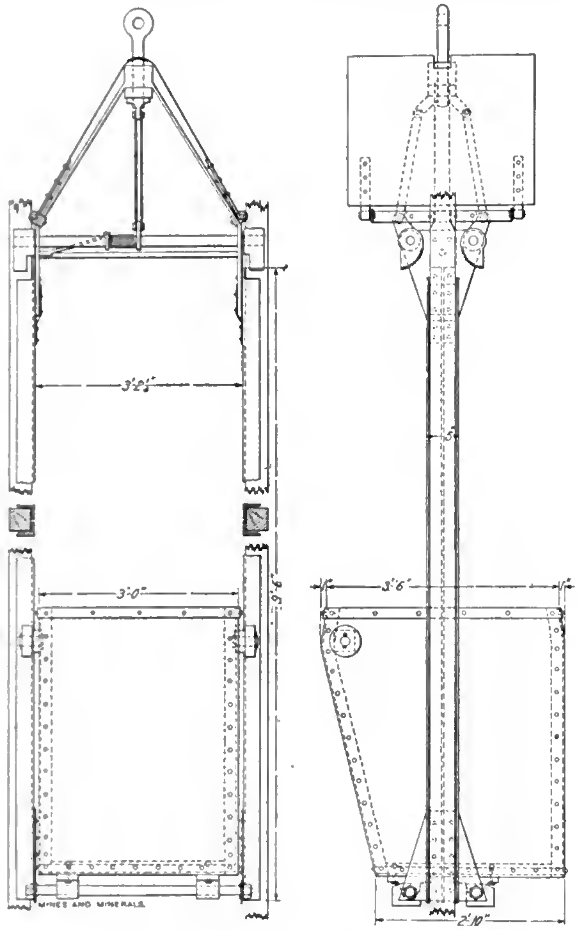

Fig. 4. Automatic Dumping Skip

A heavy air-tight door was placed across the drift, its frame consisting of 8″×8″ timbers between which and the rough walls the spaces were closed with cement. On one side, the door frame was recessed to admit of a short piece of 5-inch diameter pipe, so as to establish a connection between the air in front and behind the door. The 1-inch diameter compressed-air pipe was then led to this 5-inch orifice, inside of which a spider supported a ⅛-inch diameter nozzle connected with the air pipe. The pressure in the air main at this point was about 90 pounds. A valve in the main placed just outside the door allowed the operation of the device when desired.

When turned on, the compressed air rushing at a high velocity from the nozzle operated on the well-known injector principle to draw the mine air through the 5-inch pipe and increase the atmospheric pressure behind the door. This was found to effectively prevent the emanation of CO_2 gas into the drift.

A complete system of mine telephones is installed in the mine and is found to save considerable time previously consumed in traveling to and from the surface. A Stromberg-Carlson phone is placed at each mine station and the line connected on the surface to both the office and the machine shop. By this means the shift bosses can communicate with the office from underground, while the drill runners can telephone the machinist for any needed parts or repairs. The saving of time in eliminating many useless trips through the shaft has already effected a cash saving equivalent to a large part of the first cost.

Hoisting is done in the automatically dumping skip illustrated in Fig. 4. It has a capacity of 32 cubic feet and is made at the company machine shop. While there are no particularly new features about it, it may be worth while to call attention to its false bottom. Between the true and false bottom is placed a wooden plank 1½ inches thick, upon which rests the false bottom of ½-inch boiler plate. The wood absorbs much of the concussion on the metal, thus increasing its life, while the false bottom may be quickly replaced when worn out, thus greatly increasing the life of the skip body.

The surface hoist is a 14 in.×30 in. double drum—round rope—of the Ottumwa Iron Works type. It is equipped with an automatic stop to prevent overwinding. The skip is counterbalanced by the counterweight, shown in Fig. 5, which is operated in the manway compartment. Aside from the well-known advantages of operating a counterweight to effect balanced hoisting, this particular weight combines the advantages of requiring a small portion of the space in the manway, and safety in case of a break in the hoist cable. The skip is run at an average speed of 1,700 feet per minute and as this requires close to 200 horsepower, while the boiler furnishing the steam is only of 100-horsepower capacity, it may be of interest to digress long enough to explain this point.

This boiler is one particularly well adapted for steam generation when burning the lignite coals commonly available

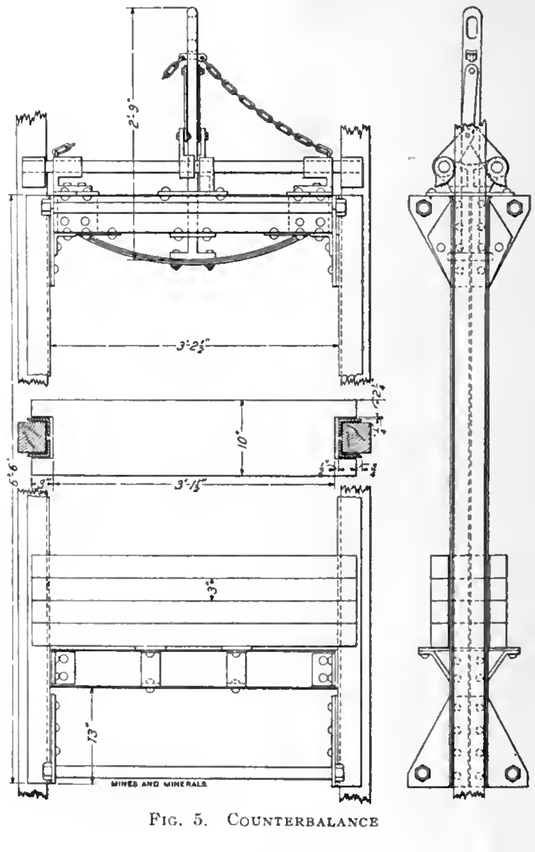

Fig. 5. Counterbalance

in the West at a cost of about half that of bituminous steaming coals. Briefly stated, its construction allows the use of a thick bed of coal. Steam introduced beneath the flat grate serves the double purpose of eliminating clinkers and combining with the volatile hydrocarbons driven off at a low temperature to form a water gas which immediately burns beneath the boiler

tubes. The introduction of preheated air at a point close to where the gases form and burn adds considerably to the efficiency of the boiler.

From what has been said concerning the requirements of the Cresson hoist, it will be understood that during hoisting the steam pressure under ordinary conditions varies widely, say from about 98 to 76 pounds, thus subjecting the boiler to considerable strain. In order to obtain a more uniform pressure the regulating device shown in Fig. 6 was made and installed. Its purpose is to increase the steaming capacity of the boiler during hoisting by starting a forced draft under the grate which lasts only while the steam pressure is below 98 pounds. Whenever this pressure is attained, the forced draft is automatically shut off by the device. The draft is induced by a steam jet in an 8-inch air pipe, the jet acting as an injector to force the air under the grate.

Referring to Fig. 6, steam pipe *a* leads from the valve *b* to the jet in the blower pipes. The valve is kept closed so long as the boiler pressure approximates 98 pounds, but the instant the pressure falls, the valve automatically opens to allow the boiler steam to induce the forced draft. Besides this connection with the boiler there is a pipe *c* which admits steam to the piston *d*, which is attached to the lever *e*, from whose end are suspended the weights *f*. The latter are equivalent to a pressure of 98 pounds per square inch. When the steam pressure exceeds 98 pounds the piston *d* keeps open the needle valve *g* and admits steam to the cylinder of piston *h* by the pipe connection shown. Here the steam pressure overcomes that of spring *i* and keeps the valve firmly against its seat. The instant the pressure decreases below 98 pounds, the weight *f* closes the needle valve, allowing spring *i* to open the valve *b*, thus admitting steam to start the forced draft.

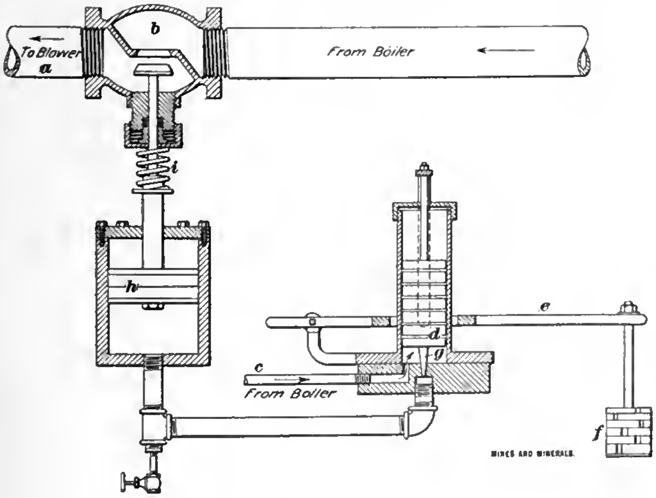

FIG. 6. BOILER PRESSURE REGULATOR

This simple regulator has been found very efficient in maintaining a fairly steady boiler pressure as shown by a Bristol recording gauge attached to the boiler.

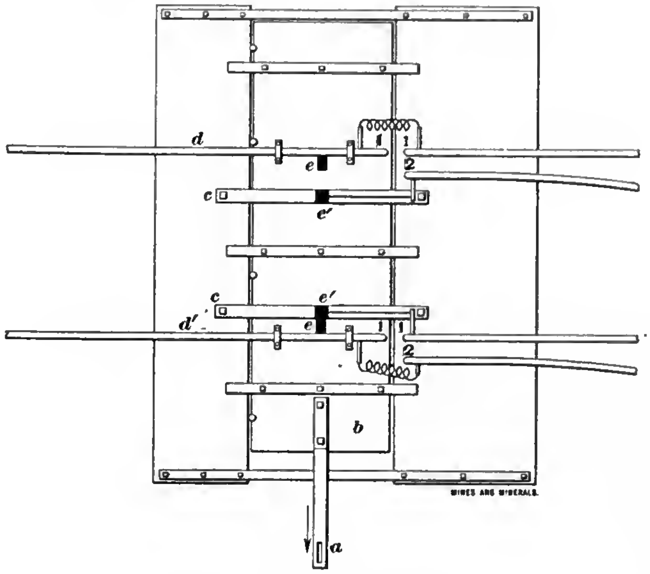

FIG. 8. TROLLEY-WIRE SWITCH

The ore when it arrives at the surface is automatically dumped from the skip into the trolley car, shown in Fig. 7. The car body is constructed of wood, lined with $\frac{3}{16}$-inch sheet steel. No advantage is claimed for it over ordinary cars except that it can be quickly and cheaply constructed by the mine carpenter.

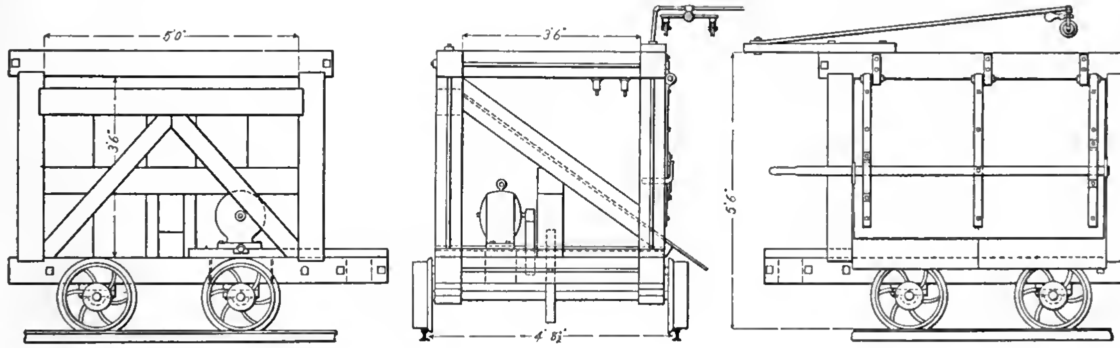

FIG. 7. TROLLEY ORE CAR

Manager Roelofs stated that one of these cars handled over 60,000 tons of rock in one year's time. The 4-horsepower motor on the car is operated by a car man who stands by the controller placed on the rear platform. Three-phase current is delivered to the trolley wires at 110 volts. There are two overhead wires while the rail serves as the third conductor.

In Fig. 1, showing the outlay of the surface plant, it will be noted that one track seen at the left leads from the head-frame to bins above the end of the sorting house. The sticky, clayey, first-class ores are dumped into these bins, thus being shunted around the sorting plant. The other ores are dumped into the bins seen in the central foreground, which feed the sorting belts. This separation of the ores requires a switch in the track and a corresponding arrangement for the trolley wires.

By means of an ingenious device, shown in Fig. 8, the trolley-wire connections are shifted properly and automatically by the same movement of the lever that sets the track rails.

This device is shown in plan, inverted from its true position. The board *b* is given a reciprocating motion by means of a vertical lever attached to the strap *a*, this lever being thrown by the movement of the track lever. As the board *b* slides

to and fro it is upheld in place by straps *c*. In the illustration the two trolley wires *d*, *d'* are shown in the proper position for sending the car to the sorting house bins. When the track lever is thrown for the other set of bins, the board *b* slides in direction shown by the arrow bringing the ends *1* of the wires opposite the ends *2*. This movement by means of the wiring connections shown and the making and breaking of contact by the springs *e* and brass strips *e'*, throws the current into the wires *2*, cutting it off from wires *1*.

No attempt is made to wash and closely sort the sticky clay ore. It is fed from the bins down a picking chute where the easily apparent waste such as basalt is picked out while the remainder falls into the tramway bins below.

The other two classes of ore are separately washed and sorted. The fine ores washed from the ore are settled in a series of tanks, steam-dried in pans, and shipped. The value of the fine material thus recovered pays the entire expense of the sorting house. The clear water flowing from the last settling tank is pumped back to the trommels, the quantity of water allowed to flow to waste being small.

The sorted ore falls into a series of bins for each class of ore. From these bins the ore is drawn into the aerial tramway buckets and sent over the line to the ore house a half mile below. The total cost of tramway transportation is but 15 cents per ton as against 65 cents for team haulage.

A very complete system of daily reports has been inaugurated at the Cresson mine and found efficacious both in increasing the efficiency of the working force and in reducing running expenses, repairs, etc. There is one form of report for the drill runners, its object being to fix the responsibility for every breakage and so ascertain whether it is due to carelessness and inefficiency or to faulty construction.

If the drill is in bad order on starting work the drillman waits till the shift boss comes into his place before doing a stroke, when he reports the damage. Otherwise he is blamed for it. In this way the runner on the previous shift is made responsible and is warned to report the damage next time and so enable its repair before the next shift goes on. This system has reduced the loss of working time by providing machinery in good order.

In like manner every trammer makes a daily report. While this at first led to considerable "mental aberration," to put it mildly, when it was learned how easily the report was checked at the end of the day, the trammers quickly got into the George Washington class.

The use of the ammunition order blank quickly has a tendency to cut down unnecessary consumption of explosives and supplies.

It is common experience that when other excuses give out the miner has a kick coming against the blacksmith department for its alleged failure to make repairs or sharpen steel.

By having the blacksmith's report it is an easy matter to determine who is the Ananias and furnish the "hike" to the proper party.

Finally the shift bosses are required to fill out a report which enables the superintendent to place his finger on that part of the mine where operations have dragged, as each working place is numbered. Thus, D 706 refers to the 6th drift on the 700 level. If this place has "tapered off" apparently without good reason, the shift boss in charge is requested to furnish a "what for."

For the guidance of those in charge of the oncoming shift, a book is kept which is always consulted before the final arrangements for the shift are made. In this book the foreman notes the important events of his shift before going off duty.

If a certain piece of roof needs watching or timbering, a stated ladder is broken, a shot missed fire in a given drift, etc., such facts are noted and warning given to look out and attend to them.

Such data are handed down to the shift bosses, and from them to the men assigned to the places mentioned. Those not anxious for sick benefits can then avoid unnecessary dangers.

The summary of the day's work is made out on another form. In case the superintendent or manager is away from the mine for a day or two these cards refresh his memory upon his return.

That the Cresson costs are considerably below the average for the district is due principally to the property having large bodies of easily and cheaply broken ore, and to keeping the working force at a minimum by means of proper mechanical appliances, which in the end reduce expenses.

By keeping close tabs on the performance of each individual on the company pay roll, his efficiency is encouraged and his expense kept at a minimum. Finally, by managing to get along with a modest though efficient surface plant, the cost of a more elaborate equipment is saved for dividends. The mechanical appliances described in this article are the results of the combined ingenuity of Mining Engineer Edward G. Morton and Master Mechanic George L. Hatfield, to whom the writer is indebted for his data and illustrations. For the remaining data the writer is indebted to the courtesy of Manager Richard Roelofs.

CONCRETE SHAFTS IN IRON ORE MINES

In a number of places in the Lake Superior iron ore district it is difficult to sink shafts owing to the amount of quicksand which must be penetrated to reach the ledge holding the ore body.

The Cliff shaft of the Cleveland-Cliffs Co., in Ishpeming, had much to contend with, but it did not offer so many obstacles to downward progress as some other locations.

The original shaft at the Negaunee mine was sunk where it met quicksand which was very wet and boiled up with considerable force as pressures were placed upon it. To overcome the various obstacles encountered in sinking required a long time and the expenditure of a large sum of money.

The original shaft at the Aragon mine in the Menominee Range was a difficult proposition to sink. It was, however, finally gotten down by perseverance and much money.

The big Chapin mine at Iron Mountain had troublesome ground, and at one point it was necessary to freeze the quicksand. This was done by using a foreign patent which was exceedingly expensive, as well as the operation.

The shaft at the Maas mine, Negaunee, was one of the most stubborn in opposing downward progress. It required six or seven years for the Cleveland-Cliffs Co. to get this shaft down 160 feet and in hoisting order. The condition of the shaft was unsatisfactory after all owing to its not being in line; therefore the mine was shut down and a contract made for a concrete shaft from the surface to the ledge. The concrete work will be forced down from the surface by the weight of the material used in its construction. The outer portion of the shaft will be round, while the interior will be 14 ft. 10 in. × 10 ft. 10 in., so that the line drawn through the cement work at either end of the shaft's dimensions will find at the shaft's bottom concrete having a thickness of 7 feet 11 inches. This thickness will be carried a considerable distance upwards from the bottom and then be gradually lessened until nearer the surface it will be tapered to 2 feet 6 inches.

The concrete work will be reinforced with steel, thus making a substantial shaft lining and the concrete will be carried well into the ledge to make a strong bottom joint. When finished, the concrete portion of the shaft will be 200 feet long from top to bottom and will be one of the largest concrete jobs in the Lake Superior country; the cost will be heavy owing to the nature of the work to be done and the conditions. The same company is concreting its Negaunee shaft, located a short distance from the Maas mine. The Cleveland-Cliffs Co. have now a concrete shaft at the North Lake mine, a short distance west of Ishpeming, and several in the Swanzey field, four are being put down on the Cuyuna veins, Minnesota.

EXAMINATION OF MINE OFFICIALS

Written for Mines and Minerals

An Examination System Inaugurated by a Mining Company Though Not Required by Law

In the state of Washington certificated mine officials are not required by law, but the Northwestern Improvement Co., with headquarters at Tacoma, Wash., and mines in Washington and Montana, has recently set in motion a system of examining their lesser mine officials. So far, this has been confined to the Washington field and to the examination offire bosses and can didates for that position, but the intention is to enlarge its scope sufficiently to include foremen and assistant foremen in the near future.

Thus far four examinations have been held, two at the Ravensdale mines and two at the Roslyn mines. The first examinations in each field were for incumbents of the positions at that time, the second were for the purpose of filling vacancies that occurred and providing an eligible list. In all 28 men have taken the examination and 21 of these have been awarded a certificate setting forth their qualifications to act as firebosses for the company.

The examinations have been entirely practical in their nature and no deep mathematical or scientific knowledge has been demanded of the candidates. Chief stress has been laid on practical experience and, next to that, a clear conception of the duties required in filling the position. The simple, yet practical nature of the questions asked is shown in the papers prepared for a recent examination. After satisfactorily passing the examination, an attractive certificate, as shown in Fig. 1, is given the successful candidate.

The following are typical of the questions asked:

Questions for Fire Boss Examination

Note.—Read all questions before answering any. Write your name, and the number of the mine in which you work, on the back of the last sheet.

Ques. 1. What is your name? Your age? How long have you worked in coal mines, and where? Were the mines gaseous or non-gaseous? Flat or pitching? In what capacity in each field?

Ques. 2. What are the duties of a fire boss?

Ques. 3. Name, and tell the characteristics of three gases commonly found in coal mines? What is the cause of each? How would you determine if any of them were present? Where would you look for each?

Ques. 4. What would be your procedure if, on your morning round, you found a room, up 60 feet on a 15-degree pitch, with no cross-cuts, full of gas back from the face for a distance of 30 feet?

Ques. 5. Explain how you would clean and test your safety lamp before taking it into the mine to test for gas?

Ques. 6. The dimensions of an airway are 8 feet wide and 5 feet high. At a velocity of 200 feet per minute, how much air would pass a given point in an hour?

Ques. 7. What are the principal precautions that may be taken to avoid explosions of gas and fires in mines?

Ques. 8. What regulations do the State Mine Laws make regarding the use of safety lamps in mines?

Ques. 9. Give the substance of the Company Rules regarding the use of powder in the mines.

Ques. 10. Explain the theory of natural ventilation, and the effect of atmospheric changes, and changes in temperature, on ventilation.

The following statement of the duties of a fire boss would be considered a satisfactory answer to Ques. 2:

"The duties of a fire boss in the mines of the Northwestern Improvement Co., in the state of Washington, are as follows:

"To make the examination of all working places before the time at which the mine begins to work in the morning as required by the state laws and the company rules. In detail, his duties on this examination are, in the order named, to examine and adjust his safety lamp and to make his entire examination with a safety lamp from the time of entering the mines; to ascertain that the ventilation apparatus of the mine is in working order and, approximately, that the usual current of air is in circulation; to thoroughly examine each working place, going in with the air, and beginning at the outside place on each split; to note all falls of rock and places where the roof is in dangerous condition through lack of timber or otherwise; to test for gas at the face of each room; to mark the date on the roof at the face of each room as a record of his examination; to test for gas in each face and on top of falls or in cavities where gas is liable to accumulate; to remove any accumulation of gas if feasible, but never by brushing except the quantity be very small; and in case the gas is not removed, he must fence off that particular opening and put up a danger board to warn any one from entering the place; to also put up a danger signal warning the miners against entering a place containing any other dangerous conditions where he deems such warning necessary; to inspect the return of a particularly gaseous mine or split for evidence of a sufficient percentage of gas to produce a cap on the flame of his safety lamp; to travel the manway and escapement shafts and note their condition for safe and rapid exit; and, finally, to come outside before the miners enter, and mark any dangerous places on a board at the mouth of the mine, and also to make a report of same, and of any gas found, in a book kept for that purpose at the office, and to the foreman. Furthermore, it is the duty of the fire boss to act as an assistant to the foreman, having particular charge of all things pertaining to ventilation, bratticing, timbering, etc., and to perform such other duties as the foreman may assign to him.

Northwestern Improvement Co.
Certificate of Competency in Mining
This is to Certify, That Mr.____ ____________
on____________191__, at ____________, Washington, successfully passed an examination for competency as ____________, as given under the rules of the Company, and is hereby pronounced qualified to act in that capacity in any of the mines of the Company in the State of Washington.
____________191 (Signed) ____________
General Manager

Fig. 1. Facsimile of Certificate

"In the absence, or at the request, of the foreman he must make the weekly air measurements and inspection of the accessible old workings of the mine as required by law."

The increase in interest and efficiency induced by these examinations has so far been very gratifying, and it is expected that like good results will be attained when the examination is extended to include foremen.

Mr. C. R. Claghorn, well known in Pennsylvania, is general manager of the company, and Mr. J. F. Menzies, of Roslyn, is general superintendent for the state of Washington. The work of giving the examination and grading the papers is attended to by the company mine inspector, Mr. J. B. Warriner.

COAL NEAR TAMPICO, MEX.

It is claimed that a good vein of coal has bee 50 miles from Tampico, Mex., but as the locality i transportation, it will probably be some time is developed.

PENNSYLVANIA'S BITUMINOUS MINE LAW

The new Pennsylvania Bituminous Mine Law, recently made operative by Governor Tener's signature, is a decided improvement over the first bill drafted. There are a number of matters that will be criticized when sufficient time has elapsed for both miners and operators to digest the law.

As a preliminary criticism, the verboseness of the lawyer and the vernacular of the mine inspector are too prominent. The result of this profuse use of words is that a number of important passages in the law are made ambiguous. There was a time when the creation of mine inspectors was opposed with all the influence operators could command, because they believed their rights would be infringed. At present, however, they favor the increase in number and the increased power given to inspectors. This change in policy shows that the operators are using their utmost endeavors to conserve the lives of their men and property irrespective of any mine law and that they welcome suggestions that will benefit their business. The increased power given inspectors removes a great responsibility from the operators' shoulders and places it on the mine inspectors, and it also refutes the statement so often made by sensational writers that mine officials care more for money than they do for the lives of their men.

The writer, when a mine official, was often compelled to do things that, had the property been his own, he would not have done. This was because he was an agent for others, and had he not done as he did he would have been an unjust steward. If the critic will examine into the affairs of any corporation he will find that there are conditions that can be improved when the lion and lamb lie down together, and not before. Looking at the new law from the miners' side, we find that he is now compelled to obey the rules laid down for his guidance by the state and by the company. In addition to that, he must protect himself; that is, not depend on the management entirely for safety; and if this phase of the rules can be carried out it will do more for the safety of the miner than any previous law has been able to accomplish.

As we interpret the law, the mine boss stands the brunt of the responsibility about the coal mine. He must be alert to keep the mine in safe condition, and not take chances of any kind that in any possible way might result in loss of life or injury. In case he has any doubts in regard to the matter his only safe way will be to call on the inspector for advice and thus shift the responsibility.

If a railroader does or leaves undone anything that might cause an accident he is disciplined, or if through his neglect an accident occurs, he is discharged. The same drastic measures should be applied to mine workers, and while mine foremen are not always responsible for accidents in their mines, there have been many that could have been avoided had the mine foreman asserted his prerogative.

Mine inspectors, when working under the old law, claimed that they were hampered in many ways by mine officials who would not carry out their suggestions regarding safety. The new law will not permit them to furnish an excuse of this kind, for, as we understand it, the law was drafted by the inspectors to overcome such obstacles, and the operators, miners, and public now expect them to make good, and decrease the number of accidents.

The English laws are preeminently clear in expression and just to miners, operators, and the public. This is because they are drafted by experienced mining engineers and submitted to miners and operators for approval. They are not intended to suit alone those directly interested, but include the general public as well. Lawyers, whose sole business is to interpret laws, are not permitted to have a hand in their drafting, and consequently the laws are not befogged with useless words, as is the new Pennsylvania mine law. Among the new features we find: That there must be apparatus to provide means of signaling from top to the bottom, as well as from the bottom to the top; that there must be an efficient safety device to prevent overwinding; the speed of the cage when lowering or hoisting persons must not exceed 900 feet per minute; boilers must be inspected every 6 months; no boilers used for generating steam are to be placed in a mine without the consent of the inspector; the quantity of air for a non-gaseous mine is not to be less than 150 cubic feet per man per minute; in a gaseous mine the quantity of air is not to be less than 200 cubic feet per man per minute. No provisions are directly made for mine animals, oxidization, and emanations of gases, the determination of the quantity of air for such purposes being left to the inspector. There is to be no permanent door in the main entry unless allowed by the inspector. In 6 months after the act is signed not more than 70 persons shall work in one split unless the inspector says so. Cut-throughs in room pillars are to be made "at such distances apart as in the judgment of the inspector may be deemed requisite, but not more than 105 feet or less than 48 feet each for the purpose of ventilation." Every ventilating fan must be provided with a recording instrument, which is to register the number of revolutions or the effective ventilating pressure of the fan. "No main ventilating fan shall be placed inside the mine; and no auxiliary fan, unless driven by electricity." This stops the use of hand-driven fans in headings, rock tunnels, etc., if the law be construed literally. "No product of petroleum or alcohol, or any compound that in the opinion of the inspector will contaminate the air" is to be used as motive power. If the owner of surface land sewers into a mine he commits a misdemeanor and is liable to a fine of $1,000 and to undergo an imprisonment not exceeding 1 year.

The entire article on electricity is new. If any one owns or leases coal lands, and the laws cannot be complied with otherwise, he can make openings on another's land for drainage, ventilation, or ingress and egress.

Inside stables are to be excavated in rock, and if in coal the walls must be lined with concrete.

Not more than one barrel of lubricating oil is to be in a mine at one time; no greater quantity than 5 gallons of explosive oil is allowed at one time; oils used in open lamps "shall have a burning point not lower than 300 degrees, and must not produce over eleven one-hundredths of one per centum of their weight of soot when burned in a miner's lamp with a flame 1½ inches high. All illuminants to be used in open lamps shall be branded with "percentage of soot." There are to be 25 inspection districts with the inspectors' salaries fixed at $3,000 per annum. Their duties are prescribed in the law.

"SAFETY THE FIRST CONSIDERATION"

A WORKING system to promote carefulness on the part of the employes has been devised by P. J. Tormey, of the H. C. Frick Coke Co. At the bottom of the shaft when the men are about to step off the cage an electric sign flashes the words "Safety the First Consideration." At danger points within the mine other signs flash the words "Safety First." This is to impress sensibly on the minds of the men the fact of precaution and to admonish them to observe the rules established as a condition of employment.

In the recent Price-Pancoast disaster it was evident that too much confidence on the part of the men was placed on the management taking care of them. When told that the work was over, instead of hurrying out of the mine they took their time, and being unacquainted with the outlets of the mine were unable to reach a place of safety. The D. L. & W. Coal Co. and the D. & H. Coal Co. are now putting signs in the mines with arrows showing the way out in different parts of the mines. This is one more step toward preserving the lives of the miners, and we believe it should be universally adopted; further, the miners should be made thoroughly acquainted with all the live workings and how to get out in case one avenue of escape is stopped. If this practice is followed out, undoubtedly a large number of lives will be preserved.

FEDERAL AID FOR MINING COLLEGES

CONGRESSMAN M. D. FOSTER, Chairman of the Committee on Mines and Mining, introduced a bill at Washington which should appeal to mining men. The purport of bill H. R. 6304 is to extend the same aid to state mining schools as is now given state agricultural colleges.

The days when cotton, corn, and wheat were the sole medium of barter between the United States and other countries has passed, for the products of the mines have steadily increased in importance until their aggregate is more than corn or wheat. Agricultural products

find a market only where manufacturing and mining communities exist; mineral products find a market everywhere, even among farmers. The products from the farm are consumed and form but temporary wealth; the products from the mines, with a few exceptions, form permanent wealth that makes for civilization.

Whenever the value of this country's mineral products is appreciated by the general public, there will no doubt be created a Department of Mines, but until that time arrives there is no reason why in the distribution of benefits the miner should not receive his as well as the farmer.

BOOK REVIEW

Magnetic Properties of Heusler Alloys, by Edward B. Stephenson, has just been issued as Bulletin No. 47 of the Engineering Experiment Station of the University of Illinois. This bulletin is a contribution of data on the subject of magnetic alloys, and describes fully the methods of magnetic testing, thermal analysis and photo-micrography used in the work. The results show that an alloy of ferro-magnetic properties comparable with those of cast iron can be made of the non-magnetic components copper, manganese, and aluminum, and that the magnetic properties depend largely on the heat treatment. Copies of this bulletin may be obtained gratis upon application to W. F. M. Goss, Director of the Engineering Experiment Station, University of Illinois, Urbana, Ill.

The Bureau of Mines has begun the publication of a series of short papers to be known as "Technical Papers," intended to convey to engineers and others quickly the results of certain of the investigations. The first of these, known as Technical Paper No. 1, has just been issued under the title, "The Sampling of Coal in the Mine," and the author is Joseph A. Holmes, the Director of the Bureau. Those interested may obtain copies of this technical paper by applying to the Director of the Bureau of Mines, Washington, D. C.

The United States Geological Survey Press Bulletins are now issued in a more convenient form than hitherto. They contain abstracts of official reports made by the Geological Survey, and if there was an index of their contents on the first page of each number it would add to their convenience.

Hurd's Iron Ore Manual, by Rukard Hurd, C. E., St. Paul, Minn., Secretary Minnesota Tax Commission. Price $7.50. This is a general reference, guide, and hand book of the Lake Superior iron ore districts. It contains 162 pages of reading matter, tables and statistics of special value to those engaged in iron-ore mining in Michigan and Minnesota, and to those who are purchasers of iron ore from these fields. The iron ore districts of New York, New Jersey, Alabama, Tennessee, and Colorado, on account of their limited extent and production, and ownership by consuming interests, without a basic system of valuation of ores, are not considered. In the absence of published explanation the "basic system" has seemed very intricate, confusing, and mysterious to mining men generally, and all along the line, from mine to furnace, time and labor are consumed and wasted in miscalculating values and misapplying premiums and penalties. Even ore experts do not agree in their interpretations of the system. The book gives simple mathematical calculations to remove the confusion, besides much other data.

Coal Mining in Arkansas, Part 1. Issued by the Arkansas Geological Survey. This book is written by A. A. Steel, who has been in charge of the coal-mine investigations in Arkansas. It is divided into eight chapters and is a comprehensive review of coal-mining conditions in that state. The scope of the book is as follows: General Conditions Relating to the Coal and Coal Mines; Details of Mining; The Miners; Work and Wages of the Miners; Relations Between the Miners and the Operators; Mining Laws of Arkansas; The Mine-Run Law; General Condition of the Mining Industry; Glossary of Coal Mining Terms. The book is well written, illustrated, and printed.

Temperature-Entropy Diagram, by Charles W. Berry, 393 pages, 125 illustrations, price $2.50. Published by John Wiley & Sons. This is the third edition of Professor Berry's valuable book on the Temperature-Entropy Diagram. In the third edition the text of the second edition is extended so as to include much new matter. It treats of the following: Discussion of Reversible Processes and the Effect of Irreversibility; The Temperature-Entropy Diagram for Perfect Gases, Saturated Steam, and Superheated Vapors, and the Flow of Fluids; Mollier's Total Energy Entropy Diagram; Thermodynamics of Mixtures of Vapors, of Gases and Vapors, and of Vapors; The Temperature-Entropy Diagram Applied to Hot-Air Engines, Gas-Engine Cycles, Non-conducting Steam Engine, the Multiple-Fluid and Waste-Heat Engine, and the Actual Steam-Engine Cycle; Steam Engine Cylinder Efficiency; Liquification of Vapors and Gases and the Application of the Diagram to Air Compressors and Air Motors; Discussion of Refrigerating Processes and Kelvin's Warming Engine; and the Entropy Analysis in the Boiler Room. The work also includes a table of the properties of saturated steam from 40° F., and a table of Hyperbolic Logarithms. The work treats very clearly and fully the application of the Temperature-Entropy Diagram to these various conditions, and engineers interested in the design of various classes of machines mentioned would no doubt find this book of interest and service.

OBITUARY

NATHANIEL W. LORD

Nathaniel Wright Lord, born in Cincinnati, Ohio, December 26, 1854, died in Columbus, Ohio, May 23, 1911. Mr. Lord was of the class of 1876 Columbia School of Mines, and after some practical mining experience in Central America was made in 1879 Professor of Mining and Metallurgy in the Ohio State University. He became chemist of the Ohio Geological Survey in 1883, and for the past 8 years has been chief chemist or consulting expert of the Technologic Branch of the United States Geological Survey, now the Bureau of Mines. Professor Lord has done much for the mining industry of Ohio, and his death will be regretted by all who knew him intimately.

G. B. BOND

G. B. Bond, of Ballarat, N. S. W., a young man of much promise in the mining industry of New South Wales, died of peritonitis in the latter part of April. Mr. C. W. Mayo, M. E., and mine manager, in announcing his death, says: "At the time of his death, Mr. Bond was engaged in erecting a mill in New South Wales. He was associated with me for a number of years and occupied trustworthy positions as engineer at the Duke of Wellington Mine, Victoria, as mill foreman for the Colonel North Silver-Lead and Railway Co., in Tasmania, and as cyanide foreman at the British Lion Mine at Blackwood."

P. M. BOYLE

With regret we announce the death of P. M. Boyle, Mine Inspector of the Eighth Anthracite District of Pennsylvania. Mr. Boyle was well and favorably known in Northeastern Pennsylvania. He obtained his education while assistant foreman for Coxe Bros. & Co., in Drifton, Pa., working day time and attending the Coxe School at night. He was a zealous advocate of temperance and those who knew him will testify to his untiring endeavor to uplift and improve the moral conditions of his fellow man.

CORRESPONDENCE

Storing Coal

Editor Mines and Minerals:

SIR:—We would like to yard our nut and slack coal but cannot do so without it taking fire from spontaneous combustion. Our analyses show that we have 2.14 per cent. sulphur in our coal, and this mostly all goes into the nut and slack. We also have clay beds and a great deal of this gets into the nut and slack. Can you tell us how we can yard this coal so that it will not fire? Of course we know we could wash it but we do not want to do so.

P. W. V.

The Problem of Education

Editor Mines and Minerals:

SIR:—Having read with much interest the article in May MINES AND MINERALS by Mr. John Verner on "Coal Dust Explosions," I must say that I agree with his conclusion that intelligent cooperation of employes, which can only be brought about by education, is the greatest factor in preventing mine accidents. But there is another side to this question. Some months ago I arranged a series of weekly meetings for my employes, providing a hall for them to meet in, and arranging for lighting and other incidentals without expense to them. Lectures by competent mining men were provided, and the men were encouraged to tell their experiences and discuss all questions in their own way. Practical mining, as well as theory, was to be systematically studied and illustrated; the object being to thoroughly educate every employe so that he could act intelligently in every possible contingency, conserving his own safety and the welfare of his fellows. It was made plain in the beginning that the employers had no ax to grind, the sole motive being the education of the employes. I may say here that the employes are all English speaking, about one-third being negroes. The first meeting was largely attended and the discussion enthusiastic. At the second meeting there was a noticeable falling off in attendance of the more ignorant men. At the third meeting no negroes at all attended. At the fourth meeting only a few of the more intelligent of the white miners were present, the result being that the meetings were discontinued by common consent because of lack of support. The very men whom it was intended to reach, and who most needed instruction, refused to be instructed, notwithstanding every reasonable effort was made to induce them to come out. The problem is: How are you going to educate men who refuse to be instructed? I am open for light on this point. On account of the meetings being instituted by an employer, some sinister motive might have been ascribed had it not been that nearly all the men had been in my employ for many years, knew me well, and intimately; were on the friendliest terms with me, and gave me the honor of professing the utmost confidence in my justice and open fair dealing.

It strikes me that the first need is to instill into the average miner the desire for education; and I confess that that is a problem for which I have not the faintest idea of a solution.

WM. KELLUM

Superintendent Southern Coal and Coke Co.

Mining in San Domingo

Editor Mines and Minerals:

SIR:—I noticed in your May issue a letter from Mr. Haussler on Santo Domingo mining. I fear Mr. Haussler is not well informed on the present condition of the island in the West Indies.

There is now no mining law of 1904. The present mining law is dated April 10, 1910.

Quoting from Article 35, Chapter IV: "All proprietors of mines shall pay into the public treasury 2 per cent. of the gross products of the mines."

Article 38, Chapter IV: "The proprietors of the soil (the owners of the surface rights) shall have a right to 2 per cent. of the net product of the mines that are exploited on their property."

Article 43, Chapter V: "The present law annuls all other laws that may be to the contrary."

Like all such government documents, this new mining law is very voluminous. I have in my office a translation of the document; and it will give me pleasure to show it to any one interested.

I think well of Santo Domingo, R. D., as a mining country. I made a thorough examination of the San Francisco Hill, in the Cristobal district, Province Santo Domingo. I found very promising prospects, which since have turned out good mines.

For the last 15 months there has been active development work on the prospects I reported on. The present owners or lessees of this portion of the main Cristobal concession have been employing a number of hands under practical American miners. Several hundred feet of tunneling have been added at Bocara, many cross-cuts at San Francisco Hill, and several cross-cuts and shafts at Majagual.

The concession of the San Cristobal Mining Co. comprises 400 square miles. I have examined not more than 4 square miles, which has been leased, and is now under development. This is a typical mining country. There is copper with some gold and silver in all the hills here. The low lands and the river banks, especially near the River Jaina, offer rich placer propositions from Mt. Banileja to the Caribbean Sea; thus many hundreds of square miles could be profitably worked for placer gold. The gold is coarse, but very pure.

Parties wishing to obtain concessions of placer properties, usually engage native labor for washing, and to prevent mistakes or stealing, the natives are paid 60 cents for every pennyweight, plus 50 cents for a day's labor. Thus reliable results can be obtained as to the average gold values per cubic yard. The natives make use of the home-made "batea," a wooden pan about 11 inches in diameter and 3 inches in depth. The native women are adepts with these bateas.

There are mountains like Mt. Lomatina, in the Province of Azua, which are over 10,000 feet high. The mineral zone is very extended and it seems as if the whole island's saddle was mineralized. Most assuredly, Santo Domingo has wonderful possibilities as a mining country, and since the United States is and will be there for the next 50 years to come (looking after the revenues under the Monroe doctrine) and revolutions are a thing of the past, finances are safe, and investment in the island will be very profitable.

I brought back samples of copper, gold, silver, iron, chromite, nickel, and other metal ores, and I know there is petroleum on the island. Coal I have found, but owing to my not being able to thoroughly examine the deposit, I can say no more. An assay of copper ore is here attached which gave the following results:

No.	Copper Per Cent.	Gold Ounces	Silver Ounces	Iron Per Cent.	Lime Per Cent.	Sulphur Per Cent.
1	2.78	.09	.75	14.00	.08	1.60
2	24.40	.02	1.20	16.05	.04	2.00
3	1.89	1.08	.65	12.56	trace	trace
4	16.54	.75	.50	17.40	.09	1.35
5	21.28	.02	trace	12.50	.03	2.28
6	2 .60	.64	.25	9.60	.02	1.36
7	17.48	.07	.85	15.20	.03	1.15
8	1.89	.72	.70	12.40	.01	.89
9	3.60	.62	.48	18.19	.02	.05
10	18.47	.07	.28	11.85	.03	1.28
11	14.60	.03	.37	15.60	.02	1.00
12	17.39	.04	.28	12.36	.01	1.30

The climate is good, tropical of course, but no matter how warm during the day, I could not do without a blanket at night.

I would advise avoiding the use of alcohol and meat in this climate. There is a great variety of fruit at the mines, the very best I ever tasted; and one can afford to do without meat and other delicacies.

Labor is good and plentiful; native labor, 50 cents gold per day. Ernest Fahrig, E. M.

Bailey Building, Philadelphia, Pa.

Coal-Dust Explosions

Editor Mines and Minerals:

Sir:—The Mines and Minerals of May, 1911, contains an article by Mr. John Verner on "Coal-Dust Explosions," which, in my opinion, includes some errors of both fact and judgment and may create in the minds of readers wrong impressions on a very important subject. If the mistakes were those of judgment only it might be unnecessary to call attention to them as such mistakes are common and all are likely to make them, but there are certain errors of fact on which these opinions are based which I think should not be allowed to go without some correction.

The article begins with a quotation from a report published by a British commission on coal dust in 1894, which states that "coal dust alone without the presence of any gas at all may cause a dangerous explosion if ignited by a blown-out shot or violent inflammation. To produce such a result, however, the conditions must be exceptional and are only likely to be produced on rare occasions." It will be noticed first that this report was published 17 years ago, before any widespread attention had been devoted to the subject of dust explosions and that the conclusions there stated must of necessity have been founded upon a comparatively small number of observations. The opinion here stated is undoubtedly in the main correct, as is shown by the fact that dust explosions occur as rarely as they do. But the writer of the article referred to bases on this report and on certain other data the opinion that the principal factor to be considered in an investigation of dust explosions is not the coal dust, but apparently the air with which it burns.

After a discussion of the air-currents produced by blasting, the author advances the statement that a dust explosion can occur only in case the air in which the dust is suspended is subjected to more or less compression, using the following language: "It is the presence and influence of this dynamic force (*sic*) that produces high explosive effects and in its absence the mere contact of flame and coal dust has proved comparatively harmless. The results of experiments and laboratory tests clearly and convincingly show that explosive effects and the propagation of an explosion can only be produced by the forcible injection of air and dust into the flame. Peckman and Peck could only produce explosive effects by blowing the dust into a flame by means of a bellows, etc." The work of other experimenters is cited as showing that dust must be suspended by compressed air, and the paragraph closes with a reference to an experiment by Holtzwart and Meyer, in which an explosion was obtained when the dust was puffed between the terminals of an electric circuit, but not when the dust was shaken in the tube.

The data given here are not sufficient for a conclusion that the dust must be suspended by compressed air in order to be explosive. In the first place, as far as I can learn, the reason for using compressed air in all cases except the last was the simple fact that it offered the most convenient means of getting the dust into suspension. That it is not necessary has been abundantly demonstrated.

A large number of experiments along this line at the University of Kansas do not suggest any such conclusion. In the earlier experiments compressed air was used simply because it was convenient, but in later experiments, comprising by far the larger number the dust was placed in a box and thrown into the air by an agitator. In most cases ignition was obtained by moving aside the cover of the box and holding a naked flame at the opening. The air was under no pressure whatever, the only object sought being to suspend the dust in the air in the form of a cloud. It was found that the result of the experiment depended more upon the quantity and condition of the dust than upon any other factors. Some dusts were inexplosive in any quantities, others were explosive in small quantities, others in large quantities, others only in the presence of gas. The following examples will illustrate:

No. 1. Drill dust from W. C. & C. Co., No. 16. Explosive limit 2.9 grams.

No. 2. Dust from haulageway W. C. & C. Co., No. 15. Inexplosive alone; 3 per cent. natural gas required to make it explosive.

No. 33. Dust from Monongah mine No. 8. Explosive limits 2.1 grams and 2.8 grams, depending on the method of selecting the dust.

These experiments are selected from a considerable number for the purpose of showing that the explosive limit depends upon the quality and quantity of the dust, other things being the same. The statement quoted by the author that "Unless there is an exceptionally large amount of dust in the air, experience shows that ignition does not take place from a naked flame," is undoubtedly correct. The reason, however, is that unless the dust exists in large quantities the mixture with the air is not explosive, but the quantity required depends upon the character of the dust. If the dust contains large quantities of combustible volatile matter, relatively small quantities suspended in the air will be explosive, but if it contains little combustible volatile matter our experiments tend to indicate that no quantity will be explosive. I wish to emphasize the statement that the conditions necessary for an explosion are first, an explosive dust; second, the suspension of a sufficient quantity of it in the air. The author quotes experiments of the Chesterfield and Derbyshire Institute of Engineers in which out of 134 tests ignition was obtained in 36 cases, and no violent explosion was obtained even with 6 per cent. of gas. A horse pistol was used to ignite the mixture. The conclusion is drawn that failure to produce more explosions was due to the fact that the firing of the pistol did not produce sufficient compression of the air. I do not believe that this conclusion is justified. The data are not sufficient. In the first place we have no knowledge whatever of the quantity of dust suspended, and second, we know nothing of its quality. Either it must have been very small in quantity or almost inexplosive, to show absence of violent explosion in the presence of 6 per cent. of gas, because this much gas alone is explosive under favorable conditions. I assume here that gas means methane. This statement that 6 per cent. of gas alone can be exploded is based upon a large number of experiments and our experiments have also demonstrated that gas and coal dust can replace each other in explosive mixtures. The fact that so few explosions were obtained in these experiments is very good proof that the dust was nearly inexplosive, or was present in small quantities, or else that the flame from the horse pistol was insufficient to ignite even an explosive gas mixture.

Farther on in the article the author advances the idea that increase in the density of the air due to decrease in temperature is likely to be a determining factor in the occurrence of explosions. I think it probable that increase in density of air may make a dust mixture somewhat more explosive, but that the effect due to a natural change in temperature would be very slight indeed. But the author's reason for this increased explosiveness is at least not well stated. He refers it to an increase in oxygen and a little later says: "The quantity of air rather than the quality of dust is really the measure of the magnitude of an explosion." I wish to take issue with this conclusion, and I can best give my reasons for doing so by making some statements concerning dust explosions in general.

An explosion of dust is not a detonation but a burning so rapid that a violent expansion of air and gases occurs. This

expansion is due partly to the formation of gases and vapors during the burning of the coal, and partly to the expansion of gases and vapors because of the increase of temperature. Coal dust can burn with explosive rapidity only when it is suspended in the air. Otherwise the supply of oxygen will be too small.

The propagation of the combustion through the mixture depends upon the quality and quantity of the dust. In other words, some dusts will burn only in the immediate neighborhood of the igniting flame, others will burn throughout the mixture, and this burning constitutes a dust explosion. In order that a flame may be propagated through any mixture of a combustible substance with air, it is necessary that the combustion at the point of ignition furnish sufficient heat to raise the surrounding particles to the ignition temperature. If the dust furnishes a large amount of heat, the combustion will be propagated. If it does not, burning will take place only in the immediate neighborhood of the ignition agent. The quantity of heat furnished depends upon the quality and quantity of the dust. The dust must also be readily ignitible, and it will be so if it contains large quantities of combustible volatile matter. This volatile matter will be distilled by heat and will be intimately mixed with the air. The difficulty of igniting anthracite dust is due to the fact that it contains very little volatile combustible matter. Therefore, it does not readily explode. I do not know whether it is possible to explode it or not. Experiments at the university lead to the conclusion that it is not possible, but I do not wish to say positively that its explosion is impossible.

The error in the author's conclusion that explosiveness depends largely upon the quantity of air present, lies in the fact that in most cases there is too little dust present to be explosive. In other words, the air is greatly in excess of the required amount. The dust present does not furnish sufficient heat for sustained combustion; therefore, there is no explosion. It is only when considerable quantities of dust are suspended in the air and when this dust is of readily combustible character that an explosion occurs.

One of the gravest sources of danger lies in the fact that a deficiency of volatile combustible matter in the coal may be made up by the presence of gas in the mine air. For example, in the case of one sample of dust, whose limit in our apparatus was 2.3 grams, it was found that .7 gram of dust would explode in an atmosphere containing 3 per cent. gas, .8 gram in an atmosphere containing 2 per cent. of gas and 1.2 grams in an atmosphere containing 1 per cent. of gas. The presence of so little as 1 per cent. of gas cut in two the quantity required for explosion, and 2 per cent. of gas practically divided the quantity by three. The ordinary means of detecting firedamp will hardly show 2 per cent. of gas and probably most fire bosses will not detect less than 3 per cent. It is readily seen then that dust may be a very great source of danger even when it is supposed to be harmless. I wish to emphasize in conclusion my beliefs, founded upon a large number of experiments, that the conditions necessary for a coal-dust explosion are that the dust shall be of such quality as to be explosive, and that it shall be suspended in the air. Also that gas and dust are completely interchangeable in explosive mixtures. In other words, there may be a pure gas explosion or a pure dust explosion, but I believe that in most cases the explosion is due to both dust and gas, because I greatly doubt whether any coal mine is entirely free from gas. The experiments referred to, and a large number of others, will be given in detail in the forthcoming Volume X of the University Geological Survey of Kansas.

I wish in conclusion to very heartily commend what is said by the author concerning the training and education of all persons connected with the coal-mining industry. I believe that the only way to prevent coal mine explosions and other accidents in mines is to thoroughly educate all persons concerned with the industry to a real appreciation of all of its conditions. Until this is accomplished it will not be possible to prevent explosions. It is for this reason that I have been so bold as to call attention to what in my opinion are errors in the article referred to.

C. M. YOUNG
Asso. Professor Mining Engineering, University of Kansas

TRADE NOTICES

A New Solder in Paste Form.—Recently a new kind of solder has been placed on the market. It is in the form of a paste in a collapsible tube, like the familiar tube of tooth paste, and all that is necessary for its effective use is to scrape off the surface of the part a little with a knife, squeeze some of the soldering paste on and apply a match, candle, or torch. When the paste becomes hot it fuses and solders in the same manner as the old-style soldering stick. The name of the new device is Solderall, and it is marketed by the H. W. Johns-Manville Co. through their branch houses in various cities throughout the country. Its convenience, cleanliness, economy, and many other advantages have naturally made a wide appeal to householders as well as to plumbers, tinsmiths, electricians, hardware and supply stores and others.

Goulds Mfg. Co. Plant.—The new barge canal that is being built in New York State passes through Seneca Falls and requires the destruction of part of the old plant of the Goulds Mfg. Co., of that place. To take the place of the condemned buildings and to provide facilities for rapidly increasing business, the company is about to build four new buildings—a storage house for rough castings, two machine shops 300 ft. × 100 ft., and a four-story warehouse 240 ft. × 60 ft. The buildings are to be ready by November 1.

Ohio Representative of the Goodman Mfg. Co.—The Goodman Mfg. Co., of Chicago, have arranged with Mr. Parker Cott to represent their line of electric coal-mining machines and locomotives in Ohio, with headquarters at Athens, Ohio. Mr. Cott has been for the past 5 years division mining engineer for the Sunday Creek Co., and his familiarity with the Ohio coal field and his training and experience in engineering problems in coal mining will enable him to be of assistance to the operators in this field.

Office Ventilation.—The American Blower Co., of Detroit, Mich., is marketing the "Ventura" electric ventilating set. This consists of a 12½-inch motor-driven ventilating fan designed to be fitted into a window or transom. By a simple reversing arrangement the fan can be made either to exhaust air from a room or to blow it in and discharge it in any direction desired. The apparatus is furnished complete ready for connection to a plug or electric lamp socket and can be put in place by any carpenter.

Notice of Infringement.—The Williams Patent Crusher and Pulverizer Co., 545 Old Colony Bldg., Chicago, has issued a notice to the public stating that the United States Circuit Court of Appeals, at Philadelphia, rendered its final decision in a suit brought by them against the Pennsylvania Crusher Co. for infringement of patent No. 843,729, for improvements in dumping cages for crushers and pulverizers. This decision of the Court of Appeals handed down in the March term, 1911, concludes "the record will be remanded with instructions to the Circuit Court to enter a decree reversing the former one adjudging claims 1 and 2 of the patent in suit to be valid and infringed and awarding to the complainant an injunction with the usual accounting and costs of suit." Under the law, a user of an infringing machine is liable for his acts of infringements. The maker and seller of the infringing machine in question has been found to have infringed patent No. 843,729 and the Court of Appeals, in addition, has found the infringed claims of said patent to be valid. The company states it is their intention to protect their rights as secured by the above patent and numer-

ous other patents which have been granted them on improvements made in crushing and pulverizing machinery and they warn the public against buying crushing and pulverizing machines which infringe any of their 87 patents.

Centrifugal Pumps for Mine Drainage.—The De Laval centrifugal pumps contain many excellent features, both as regards efficiency and economy, that we can only briefly refer to in this department. Centrifugal pumps have, by actual use in mine drainage, as well as for other pumping purposes, demonstrated their superior worth, and the De Laval pumps are the most widely known of the centrifugal type. Mine officials who have drainage problems to meet, no matter what their nature, especially if the water is strongly acidulated or gritty, will be well repaid by an examination of the handsome and well-arranged catalog B of the De Laval Steam Turbine Co. It is in a measure a textbook on centrifugal pumps and contains, besides the illustrations descriptive of De Laval pumps, much information of value to any man having any interest in pumping propositions. It will be sent free on request to mine officials by the De Laval Steam Turbine Co., of Trenton, N. J.

Denver & Rio Grande.—Announcement is made by the Denver & Rio Grande Railroad of improved train service between Denver and Salt Lake City and San Francisco. A new fast train—making four trains daily in each direction—has been added, and the running time reduced 2 hours. The Western Pacific has added a second daily train over its line between Salt Lake City and San Francisco, with through standard and tourist sleeping cars on both trains between San Francisco and Chicago in connection with the Denver & Rio Grande. The opening of the Western Pacific (Pacific Coast extension of the Denver & Rio Grande) has in no way changed the relations of the Rio Grande with the Southern Pacific and the San Pedro lines. Through cars over the Denver & Rio Grande and the Harriman lines will continue to be operated as heretofore, the new service via the Western Pacific merely supplementing that now in effect through the Ogden gateway.

New Home of Electric Service Supplies Co.—Electric Service Supplies Co. has recently moved into its new office and factory building, at 17th and Cambria Sts., North Philadelphia. The old factory, the outgrowth of the old Garton–Daniels Co., at Keokuk, Iowa, as well as the Philadelphia office and warehouse, formerly at 1020-24 Filbert Street, have been discontinued and all are housed in this new building. The site permits room for expansion, is but five blocks from both passenger and freight stations of the Pennsylvania and Reading railroads, and has a railroad siding on the property. This building, which is the first of a group to be erected on the site, is a six-story, monolithic, reinforced-concrete structure, fireproof in construction and equipped with automatic sprinkler system capable of extinguishing any blaze that might occur within the building. It contains machinery for the manufacture of all the varied devices of the company, as well as room for carrying a large stock of finished products, and is equipped with all the most modern facilities for light, heat, comfort, and convenience. The general offices are finely finished and conveniently arranged, and will enable a large business to be done economically.

The Gardner Crusher, for crushing or reducing coal, ore, rock, or any material, embodies in its construction many features of interest to mine or mill owners and managers. Its advantages, as shown in a concise and well-illustrated catalog, are briefly as follows: It can be fed with large pieces of coal, ore, rock, or whatever material is to be crushed. It has very large capacity. It requires comparatively small motive power. It is easy and cheap to install. Wear and tear are almost eliminated. It occupies but little space. It can be regulated to crush to any degree of fineness. It is solidly constructed, and is moderate in price. Free crushing tests are made at the demonstrating plant of the Gardner Crusher Co., whose offices, factory, and demonstrating plant are located at 550 West 34th Street, New York City. Catalogs describing the crusher in detail will be sent any mine or mill official on request.

Advertising Agency.—Wm. M. Chamberlain has opened a general trade and technical journal advertising agency, with office at 71 Griswold Street, Detroit, Mich. Wm. B. Milligan has been engaged as chief of copy department, and the agency is prepared to conduct a general business-promotion department for its clients.

Western Electric Co.—The business of Western Electric Co for May was 12 per cent. in excess of the same month a year ago and for the 5 months to June 1 sales have exceeded the same period of 1910 by 8 per cent. At the end of May the company was employing 26,000 men. When business was at the top in 1907 the company had a total of 29,000 employes, although the volume of production for that year was between 4 per cent. and 5 per cent. less than this. Increased efficiency of operation explains the difference.

Removal.—Ogden Assay Co. announce the removal of their office to more convenient and central quarters, 1711 Tremont Street, where they have one of the best fitted laboratories in the West for assaying and general analytical work. The chemical laboratory is under the direction of Mr. H. R. Brandenburg, D. Ch., who has had a wide experience, both in Germany and the United States, as an industrial chemist, and the company are prepared to work out all problems in their line for the benefit of their patrons.

NEW LEGISLATION WILL AFFECT MINING SHARES

The bill which Governor Foss, of Massachusetts, has signed relative to the listing and advertising of shares of stock of mining corporations, to take effect in 30 days, is as follows:

Sec. 1.—An officer of a mining corporation who makes a false statement, knowing the same to be false, in an application to any stock exchange to list the shares of such corporation, shall be punished by a fine not exceeding $500, or by imprisonment for not more than two years.

Sec. 2.—No officer, agent, clerk, or servant of a mining corporation, nor any person dealing in the shares of such corporation, shall cause to be published any advertisement of the shares of such corporation in which any statement is made of the value of the property of the corporation, or of its present or prospective earnings, or of a prospective increase in the price of the shares, unless the president and a majority of the directors of such corporation within 60 days prior to the date of the publication of such advertisement have filed with the commissioner of corporations, in such form as he shall prescribe, a statement under oath of the financial condition of the corporation, a full description of its property, and a statement of the earnings, if any, from the operation of the same for the fiscal year next preceding the date of the filing of the said statement.

Sec. 3.—Whoever, having caused the publication of such advertisement, or being a promoter, officer, clerk, or servant of a mining corporation, or a broker or agent for such corporation or such promoter or for the person or corporation causing the publication of such an advertisement, sells or offers for sale any shares of stock in such corporation knowing that any statement in such advertisement is false or is inconsistent with a statement filed under the provisions of section 2 of this act, shall be punished by a fine of not more than $500, or by imprisonment for not more than two years.

Sec. 4.—Whoever violates the provisions of section 2 of this Act shall be punished by a fine of not more than $200, or by imprisonment for not more than one year, and an officer or director, of a mining corporation who signs any false statement filed with the commissioner of corporations under the provisions of said section, knowing such statement to be false, shall be punished by a fine of not more than $1,000, or by imprisonment for not more than two years.

MINE SUPPORT TESTS

In order to arrive at some definite conclusion relative to the strength of the various materials used in anthracite mines for the purpose of supporting roofs, Messrs. Conner and Griffith, of the Scranton Mine Cave Commission, had Prof. Frank C. McKibben make a series of tests for them at Lehigh University. The results of these tests are of considerable importance to engineers and are therefore copied from their report. The words in parentheses are not taken from the report. The results of the engineers' findings were printed in the May issue of MINES AND MINERALS. The report, however, is so long it is impossible to make use of it all at one time, besides there are necessarily considerable data unimportant to engineers outside of Scranton.

Tests of Crushing Strengths of Supports Made of Different Materials Used in Mines

Test 1.—This test consisted in crushing a pillar made of mine rock, four sides of which were laid vertically and then filled with stone of various sizes packed in by hand so as to make the pillar of loose stones without mortar of any kind. This pillar was 5 feet long, 2 feet 4 inches wide, 18 inches high. It was laid directly on the bedplate of the testing machine and under three steel beams, which were later used in applying the load over the entire top surface of the pillar. The stone used was slate, bony coal and fireclay. The load on this pillar was applied in increments until a maximum pressure of 489,150 pounds was reached. When the maximum load was reached, which approximated 42,000 pounds per square foot, the maximum compression amounted to 5.3 inches. (This kind of roof support is used in coal mines with satisfactory results, in fact dry-pack walls are almost universally adopted in longwall mining to keep open the haulage roads and airways. In Fig. 1 is shown a dry-masonry pillar in an anthracite mine which has

FIG. 1. DRY-MASONRY ROOF SUPPORT

evidently been adopted as a temporary support. In cases where it is desirable to have a support not so likely to collapse when pressure is thrown on it, masonry pillars, such as that shown in Fig. 2, are substituted. Pillars having areas so small as those shown in Figs. 1 and 2 are of little use for more than local roof supports, and are not intended to support the entire cover up to the surface.)

Test 2.—This test consisted in crushing a timber crib, shown in Fig. 3, made of four layers of round timbers which were about 5 inches in diameter. Each of two of the layers consisted of two of these round timbers 5 feet 4 inches in length, and each of the other two layers consisted of three round timbers 2 feet 8 inches in length. The spaces between these

FIG. 2. MASONRY PILLAR

timbers were filled with slate, bony coal, and fireclay, and the crib was then filled wth small stones shoveled in, the whole resulting in a timber crib 5 feet 4 inches in length, 2 feet 2 inches wide, and 23½ inches high. The load was applied in increments. The maximum load reached 900,000 pounds and the settlement was 7.1 inches. (This kind of mine support is used in both coal and metal mines for temporary work, but is not suitable for permanent support. The timbering shown in Fig. 4 will probably last 3 or 4 years under favorable conditions, but eventually it will be attacked by dry or wet rot unless antiseptically treated previous to its being taken into the mine. Fig. 5 shows another timber crib that has been attacked by wet rot, the fungi showing above and back of the men.)

Test 3.—This test consisted of crushing a circular pillar 28 inches in diameter and 14½ inches high, made of slate arranged so that the outer surface was fairly smooth, the spaces between the stones and the interior of the pillar being filled with small stones. The load was applied in increments, the maximum load being 361,000 pounds with a corresponding settlement of 4½ inches.

After tests 1, 2, and 3, the stones were found to be very badly crushed, many having been reduced almost to powder, especially those immediately under the load.

Test 4.—This consisted in loading a pile of broken stones and observing the settlement caused by the loading. The stone used was crushed sandstone which would pass through a ring 1¾ inches in diameter and 40 per cent. voids, but under the bearing plate where the load was applied the voids were filled with small broken stones so as to get a secure bearing. The pile of stone was 25 inches wide, 9½ inches high, 2 feet 10 inches long on the top and 4 feet 5 inches long on the bottom. The load was applied on a cast-iron bearing plate 20 inches square, which rested on the top of the pile of stones. The maximum load reached was 581,000 pounds and the maximum settlement was 4.36 inches. After the tests many of the stones were found reduced practically to a powder, those stones under the bearing

plate being greatly disintegrated and the plate was pressed downward into the stones. At the ends the pile moved outward as the load was applied, but on the sides the pile was confined by timbers which prevented lateral movement.

Test 5.—This test consisted of crushing a pile of broken sandstone into varying sizes up to pieces as large as a man's

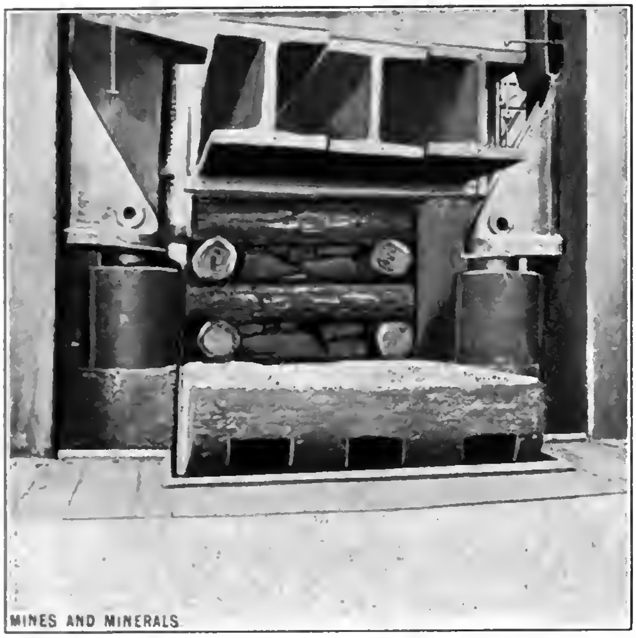

Fig. 3. Crushing a Timber Crib

head. Small stones were placed under the bearing plate. The stones were confined on the sides but were free on the ends and were not laid in any order. The pile was 25 inches wide, 11½ inches high, the length was 3 feet 8 inches on top and 5 feet at the bottom. The load was applied by a cast-iron bearing plate on the top of the pile, the plate being 20 inches square, the maximum load was 417,000 pounds and the maximum settlement was 4.6 inches.

Test 6.—This test consisted of applying a load to a pile of river sand by means of a 20″×20″ bearing plate. The pile was 8 inches deep, 2 feet 6 inches long on top, and 4 feet 2 inches long on the bottom, having a width of 25 inches, and was confined on the sides but not on the ends. The maximum load reached 600,000 pounds, and the maximum settlement was 5 inches.

Test 7.—This test consisted in crushing a pile of broken sandstone having 40 per cent. voids and sizes that would pass through a ring 1¾ inches in diameter, mixed with river sand in proportion of 10 volumes of broken stone and 4 volumes of sand. The pile was 10½ inches in diameter, 25 inches wide, 2 feet 5 inches long on top and 4 feet 6 inches long on bottom, and was confined on the sides but not on the ends. The load was applied on the top of the pile through a 20″×20″ bearing plate. The maximum load was 800,000 pounds and the maximum settlement 4.7 inches.

Test 8.—This test consisted of filling a cast-iron cylinder by flushing in coal culm with water until the cylinder was filled with the culm. The piston was then placed on top of the culm and the whole allowed to stand on a boiler for two days, after which the cylinder was then placed in the testing machine and the pressure applied to the piston, which in turn communicated the pressure to the culm within the cylinder. The culm was confined within the cylinder, the dimensions of which were as follows: Inside diameter 6.4375 inches, inside depth of cylinder 10.4375 inches, depth of culm in the cylinder 10 inches. The pressure was applied to the piston and the culm was compressed until the settlement reached 2.7 inches under a load of 200,000 pounds. This load corresponds to a pressure of 6,150 pounds per square inch, or 443 short tons per square foot.

Test 9.—This test consisted of applying a pressure to the piston of the cylinder in the same manner as in test No. 8, except that broken dry sandstone instead of coal culm was used. This broken sandstone has 40 per cent. voids and the pieces would all pass through a ring 1.75 inches in diameter. The cylinder was filled to the top, giving a depth of 10.4375 inches to the stone. The maximum load applied was 300,000 pounds, which caused a settlement of 3½ inches, at which time the pressure was 9,200 pounds per square inch. As a result of the test the stone was completely crushed and compressed into the iron cylinder so that it had to be cut from the cylinder with a chisel.

Test 10.—This test consisted of applying pressure to the piston of the cylinder in the same manner as in test No. 9, except that the broken sandstone, which had 40 per cent. voids and pieces which would all pass through a ring 1.75 inches in diameter, had voids filled with river sand. The cylinder was filled to the top, giving a depth of 10.4375 inches to the mixture of stone and sand. The maximum load applied was 300,000 pounds which corresponds to a settlement of 2.4 inches, at which time the pressure was 9,200 pounds per square inch. As a result of this test the stone was completely crushed and compacted in the iron cylinder.

Test 11.—This test consisted of applying pressure to the piston of the cylinder in the same manner as in test No. 9, except that cinders formed by burning anthracite under boilers were used in the cylinder. The cylinder was filled to the top with cinders which had 64 per cent. voids. The maximum load applied was 300,000 pounds, corresponding to a settlement of 5.3 inches, at which time the pressure was 9,200 pounds per square inch.

Test 12.—This test was exactly similar to test No. 8, except that the cylinder filled with culm was allowed to stand for

Fig. 4. Timber Crib in Mine

8 days over a boiler with the piston removed. The culm was 9 inches deep in the cylinder and the pressure was applied to the piston until the settlement reached 3 inches under a load of 300,000 pounds. This load corresponds to a pressure of 9,200 pounds per square inch. Although the culm had been drying for 8 days there was considerable water in it. The water was squeezed out during the test.

(In the table, Summary of Tests, the maximum settlement of culm is given as 33 per cent.; however, this percentage does not take into account that previous to the test there was a settlement of 10.4375 − 9 = 1.4375 inches before pressure was applied and afterwards 3 inches, or a maximum shrinkage of 42.5 per cent. According to former experiments there is a

FIG. 5. FUNGI ON TIMBER CRIB

settlement of 31 per cent. in flushed culm after drainage is complete; if to this 33 per cent. is added pressure shrinkage, culm flushing as a mine support does not look inviting. The end of a pipe line for culm flushing is shown in Fig. 6, with water and culm escaping. Culm occupies about 46 per cent. more space than coal in the solid, and for flushing requires from 1½ to 6 pounds of water per pound of culm according to the distance and inclination of the pipe. So far culm has been used as a temporary roof support where pillars are to be robbed, and not as a surface support.)

SUMMARY OF TESTS

No.	Description of Test	Maximum Load: Total Pounds	Maximum Load: Pounds Per Square Foot	Maximum Settlement: Inches	Maximum Settlement: Per Cent.
1	Rectangular pillar of mine rock..........	489,150	42,000	5.26	29
2	Timber crib filled with mine rock..........	900,000	63,300	7.08	30
3	Circular pillar of mine rock..............	361,600	85,000	4.51	31
4	Pile of broken sandstone, small sizes....	581,000	209,000*	4.36	46
5	Pile of broken sandstone, large and small sizes..............	417,000	150,000*	4.61	41
6	Pile of river sand......	600,000	216,000*	5.00	63
7	Pile of small broken sandstone and sand..	800,000	228,000*	4.69	45
8	Wet culm in cylinder..	200,000	886,000	2.73	30
9	Broken sandstone in cylinder............	300,000	1,330,000	3.66	35
10	Broken sandstone and sand in cylinder.....	300,000	1,330,000	2.42	23
11	Cinders in cylinder.....	300,000	1,330,000	5.33	51
12	Wet culm in cylinder..	300,000	1,330,000	3.00	33
13	River sand in cylinder.	300,000	1,330,000	3.35	32
14	Pillar of mine gob.....	600,000		2.43	27

* Pressure under 20″×20″ bearing plate.

Test 13.—This test is exactly similar to Test No. 8, except that the cast-iron cylinder was filled with Delaware River sand, the sand being placed in the cylinder and settled by shaking until the sand was flushed to the top of the cylinder. A load was then applied to the piston until a maximum pressure of 300,000 pounds, with a corresponding settlement of 3.1 inches, was reached. The sand was dry.

Test 14.—In this test pure sand was flushed into a cylinder. The sand was allowed to dry for a period of 48 hours. The top of the sand was 1.125 inches below the top of the cylinder. The maximum pressure was 300,000 pounds and the settlement 1.93 inches.

Test 15.—This test consisted of a pile of blue measure sandstone; the size of the pieces 3 to 6 inches square, 20.25 inches wide, and 3 feet 3 inches long on top and 9 feet deep, voids on top being filled with a small quantity of broken Potsdam sandstone for bearing. On the sides the 3-foot 3-inch dimension was confined by 6″×8″ timbers, which confined the material on the two sides and the base plate of the machine, and the I beams confined the material on the top and bottom, where on the ends the material was free to move outward, but in the test there was very little movement at the ends. The loads were applied to the top of the pile in increments and the maximum load reached 600,000 pounds, and there was a subsidence of 2.43 inches equal to 27 per cent.

AN IMPORTANT OIL LAND DECISION

First Assistant Secretary of the Interior Frank Pierce, in the case of the application of the Bakersfield Fuel and Oil Co., for a patent to 160 acres of oil land has rendered a decision of much interest to oil operators and investors in shares of oil companies. In June, 1899, eight persons attempted to locate 160 acres as a single oil placer claim. Before any discovery of oil was made, in August of the same year, these eight conveyed their alleged claim to the Bakersfield Fuel and Oil Co.,

FIG. 6. FLUSHING CULM

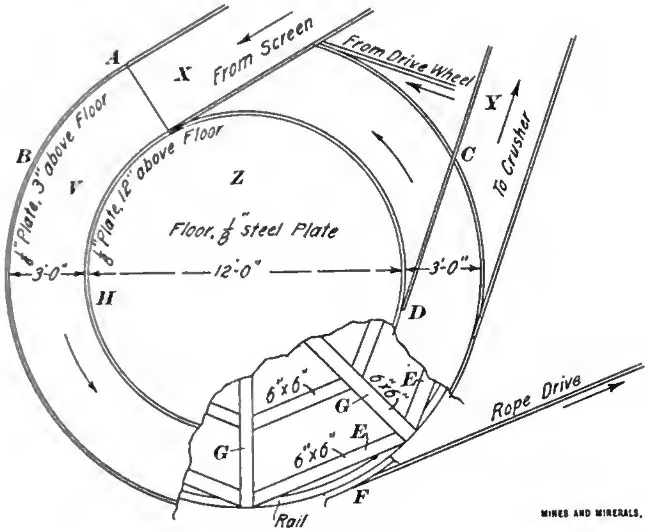
which sank a well and discovered oil in paying quantities in September, 1900. The application of the company for a patent has been denied on the grounds that the corporation has no greater rights than an individual, and is consequently entitled to but 20 acres of land, the amount conveyed in patents of placer lands after discovery of mineral and to single persons.

Mining Wrinkles

Inspection Table at the Cokedale Mine

Written for Mines and Minerals

The entire output, some 1,300 tons daily, of the Cokedale mine of the Carbon Coal and Coke Co., near Trinidad, Colo., is converted into coke. After the tipple was built it was found



Plan of Inspection Table

necessary to provide for a careful inspection of the coal as coming from the mine, that too much rock might not be sent out, thus overloading the washers and affecting the ash content of the coke. By reason of the screens, chutes, crushers, etc., being already installed, and by reason of the limited space available, the inspection table at this plant presents many points of interest.

As built, it consists essentially of a revolving table Z, 18 feet in diameter upon which the coal from the mine is fed through the chute X, and from which it passes through the chute Y, to the crusher. From the crusher it is elevated to the bins, from which it is fed into the washer. The revolving table is built similarly to an ordinary wagon wheel of $6'' \times 6''$ timbers, the spokes $G\,G$ braced by other $6'' \times 6''$ timbers $E\,E$, etc. Upon this framework is spiked 1-inch plank, and upon this planking are bolted $\frac{1}{8}$-inch steel plates. The framework is thus 7 inches thick.

The space between the braces $E\,E$, etc., and the outer circumference of the wheel is filled solidly by two pieces of $3'' \times 9''$ oak (original dimensions), the wide sides bolted together and cut with the proper radius, in this instance, 9 feet. Two grooves are cut around the circumference in this oak filling to engage the rope drive by which the table is rotated at the rate of $2\frac{1}{2}$ revolutions per minute.

To the under side of the table, and a few inches within the circumference, is bolted a rail with its base upward. The rail is continuous, of any convenient weight in use around the mines, and is bent in the form of a circle, the radius used at Cokedale being about 8 feet 9 inches, or 3 inches less than that of the table. This rail bears upon eight 16-inch pit-car wheels set radially and equidistant apart in the platform floor, serving as a bearing for the outer rim of the table.

The outer rim $B\,C$ is composed of a $\frac{3}{8}$-inch steel plate, bolted to the circumference, and set with its top 3 inches above the floor of the table. The inner rim $D\,H$ is also made of $\frac{3}{8}$-inch steel plate, but is 12 inches high. The table thus consists of an annular ring 3 feet wide with an outer diameter of 18 feet and an inner one of 12 feet.

The side of the chute X is extended with a height of 12 inches from A to B to prevent any coal dropping on the platform and is, of course, not attached to the table. The crusher chute Y is also extended with a height of 12 inches from C to D so that whatever coal may be backed up against it will not roll over on the center of the table Z. The chute X, into which the coal is dumped at about the rate of two mine cars a minute, is provided with an automatic feeding device, driven by a separate leather belt from the rope drive, so that the coal is spread uniformly over the annular space V. As this space moves with a tangential speed of but $2\frac{1}{3}$ feet per second and is but 3 feet wide, the inspector, who stands at about the point F, can not only plainly see, but easily remove any impurities.

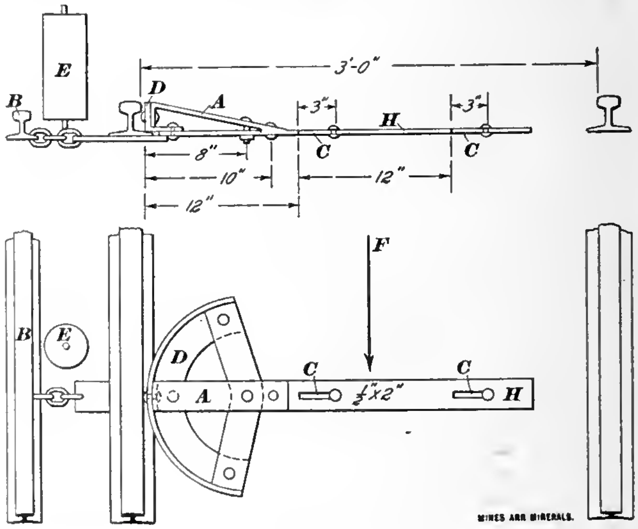
The outer circumference at Cokedale is $56\frac{1}{2}$ feet and the space from the foot of the feed-chute X to the mouth of the crusher chute Y, available for inspection, is about 40 feet. Should it be desired to use this table for picking by hand, from five to eight operators can easily stand around it. In this latter case, it would seem advisable not to floor over the inner 12-foot space Z, but to leave it open to a rock chute below into which the impurities could be thrown. To avoid injury to the timbers, if used as a picking table with open center, it might be advisable to cover the spokes $G\,G$, and the braces $E\,E$, etc., with thin sheets of iron.

We are indebted to Mr. Jacob Spahr, outside superintendent at Cokedale, for the above description.

Rope Throw at Radiant Mine

Written for Mines and Minerals

In dropping a trip down grade around a curve it not infrequently happens that the rope binds under the head of the inner rail. In event of the trip being long and the weight upon the rope consequently great, it is often necessary for an attendant with a bar to force the rope out from under the rail so that



Rope Throw

it may enter the sheaves. To do away with this extra labor an effective and cheaply constructed device is in use at the Radiant mine of the Victor-American Fuel Co., near Florence, Colo., and for a description of it we are indebted to J. Q. McNatt, mining engineer, of the latter city.

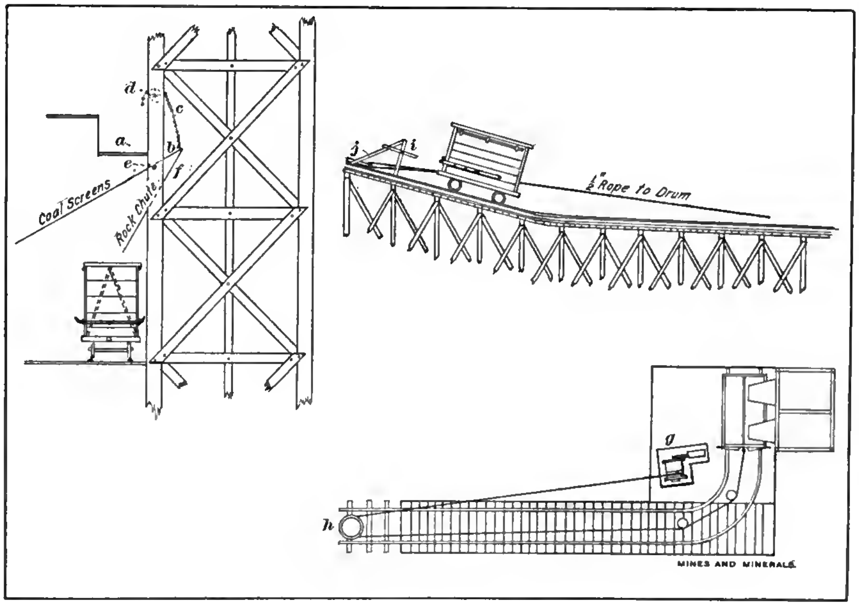
The device shown in the drawing is placed at the point where it is found that the rope binds under the rail. It consists of a plate of bar iron H, $\frac{1}{2}$ in. $\times$ 2 in. in cross-section and of a

length dependent largely upon the gauge of the track. To this bar at the inner rail of the curve is bolted and welded the segment of a circle D, made of angle iron, or a piece of a broken mine-car wheel may be used. At Radiant, this segment has a radius of 9 inches. On top of this is welded a plate A of bar iron $\frac{1}{2}$ in. $\times$ 2 in. in cross-section. Two slots, C and C, 3 inches long, are cut in the main bar. The bolts through these slots may either be driven into the cross-tie upon which the bar is placed, or, in event of the bar sliding upon a plate, as is the usual practice, they may be driven through this bearing plate. The inner end of the main bar H is attached to a spring rail B, the fulcrum of which may be so placed as to give any desired degree of tension.

After the empty trip has passed in the direction of the arrow F, the segment D, being forced out by each car, is brought back into place by the spring rail B, and after the trip has passed around the curve the rope begins to leave the center line of the track and to bear toward the inside of the curve. In so doing it is raised by the plate A above the top of the rail, and is thus, automatically, brought to bear upon the vertical roller, or spindle E. Beyond E, in the direction of the arrow F, are placed the ordinary horizontal-grooved sheave wheels, into which the rope is led by inclined guide blocks.

Rock Handling Arrangement at Globe Mine

During the development work at the Globe mine of the National Fuel Co., near Walsenburg, Colo., a very large proportion of rock to coal has to be handled. As ordinarily arranged, the cage, which is of the self-dumping type, would be stopped at the ground level, or a little above, and the cars of rock pushed to the dump by hand. To save this labor, Joseph Watson, the general superintendent, planned the head-frame so that the weigh boss handles all the rock as well as the coal.



ROCK DUMP AT GLOBE MINE

When the weigh boss, who stands on the platform a notes a car of rock coming up the shaft he raises the bottom plate b, by means of chain c, passing over the wheel d of the coal chute, which plate turns on an axle at e. The load of rock thus passes into the chute f, of which there are two, one for each compartment of the shaft, and thence directly into the rock car.

The rock car is of the side-dump pattern, with a Λ-shaped hopper bottom. This car has a length of two compartments of the shaft, to save moving, and a consequent capacity of two mine cars, although it may be built of any size that the strength of the trestle will permit.

When the car is loaded, the weigh boss leaves his station at the dumping level a, and admits steam to the small engine g. This engine, by means of a $\frac{1}{2}$-inch wire rope, passing around the sheave h, hauls the car to the end of the dump where the fixed bars i raise the latches j, thus opening the side doors and causing the load of rock to be dumped automatically. Releasing the brake on drum permits the car to return by gravity to its loading position at the shaft.

In addition to saving the labor of at least two men this arrangement is of value in that the cars underground may be gathered by the drivers in their regular rounds and do not have to be shifted out from among the loads. There is thus absolutely no interference with the mine haulage.

Stopping Blocks and Derailing Switches

Written for Mines and Minerals

The majority of the coal mines in Las Animas and Huerfano counties, Colo., are opened on the eastern outcrop of the basin, the seam having a general dip to the west of from 5 to 15 degrees. By reason of this dip and to prevent the possibility of a runaway trip wrecking the slope, numerous ingenious stopping blocks and derailing switches are in use.

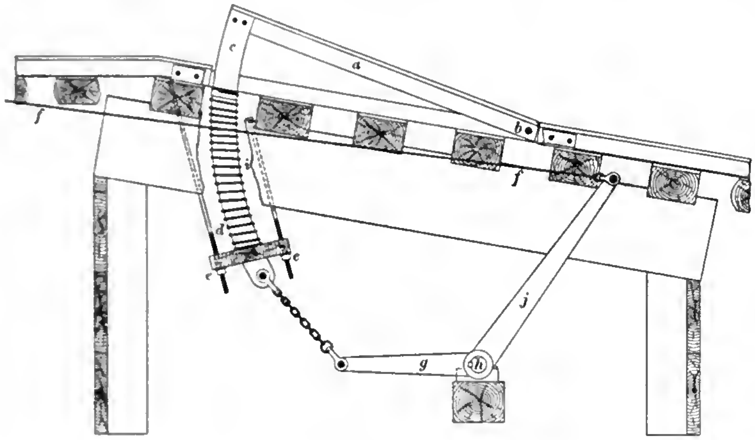
One of the best of these is manufactured under the McClure patents by the Hawkins & Barnet Machine Co., of Trinidad, Colo., and is installed at the Green Cañon mine of the National Fuel Co., near Aguilar. A side elevation is shown in Fig. 1, and the drawing is practically self-explanatory. It consists of a section of a rail a, 4 feet in length pivoted at b. The loaded trip depresses the rail, causing the sword c to descend, thus compressing the spring d. As the wheels of each car of the trip leave the rail, the compression of the spring naturally throws the rail back into position to engage the axle or bumper of the nearest car in event of the trip starting back into the mine for any reason. The tension of the spring is regulated by means of the two nuts at e, it usually requiring a weight of from 100 to 150 pounds to depress the rail a. The drawing shows one of these blocks placed near the knuckle for use on the loaded track.

When used on the empty track, which would be at a lower elevation than in the case shown in the illustration, the blocks are placed sufficiently far from the dump (toward the slope) to accommodate an entire trip. The first car of the trip is run down to the rail a, which acts as a stopping block. When the trip is ready and the rope attached, the dumpman pulls the rod f, which is attached to the rocker arm g, pivoted at h, thus depressing the rail and leaving the trip free to descend the slope. If for any reason the trip parts or the rope becomes detached, releasing the rod f immediately throws up the rail a, which engages the nearest car and stops the trip before a runaway is possible. In some instances the rod (frequently a heavy wire) is affixed to a lever at a switch stand which permits of the rail being locked down, but it is better practice to compel the dumper to hold the lever at the end of the rod until the trip has passed over, so that it may be instantly released in event of an accident. The lever operating the rod f may be set any desired distance from the block; this distance being determined chiefly by the length of the trip it is desired to handle and is not infrequently as much as 200 or more feet.

It is to be remembered that the illustration shows but one-half of the apparatus. There are two rails a, one on each rail of the track, attached to the pivot b, and consequently two

swords c, and two rocker arms g, attached to the axle h. It is apparent if there was but one rail a, say on the right-hand rail of the slope, a trip jumping to the left would not be stopped by the block. With a double rail it is clearly impossible for a trip to run away. Aside from the cheapness of these blocks, they may be installed for less than $100, and the saving in labor of operation, their positive action is to be commended. They are always in place to catch the first or last or any intermediate car of a runaway trip and cannot be put out of action except deliberately by pulling the lever attached to the rod f.

At the Piedmont mine of the Rocky Mountain Fuel Co., near Trinidad, a runaway switch, similar to those used on railroad sidings, is employed to derail the cars in event of the trip getting away. Like the above it is positive in action, the switch always being held open by a spring rail of the familiar type. When the trip is ready to descend the slope the derailing switch is closed by a lever to which is attached a rod or wire. This rod or wire may be made of any desired length, 200 feet or more, so that the switch may be closed by an operator at any point on the tipple. While this device is simple and effective



Stopping Block

and may be made by any mine blacksmith, it is not as efficient as the one first described. A runaway trip is, of course, always ditched and not stopped on the rails as with the McClure block, and further, this device cannot be used as a stopping block against which the empty trip may be made up.

At the Robinson mine of the Colorado Fuel and Iron Co., at Walsenburg, a Mitchell dump is used on the empty track as a stopping block against which the trip is made up. When the trip is ready to descend the slope the horns are opened by a lever attached to a rod or wire of any desired length so that it may be operated from any point on the tipple. Releasing the lever after the trip has passed over closes the horns so that a new trip may be made up against them. In the case in question the apparatus can only be used on the empty track and as a stopping block, as the loaded cars naturally cannot pass through the horns. While not intended as a derailing or stopping device in event of the trip getting away as it is about to descend the slope, nevertheless releasing the lever will throw the horns in, with the natural effect of holding the trip.

THE I. C. S. ANNIVERSARY BANQUET

On the 16th of October, 1911, will occur the 20th anniversary of the enrolment of the first student in the International Correspondence Schools. In order to celebrate the event President Foster has issued orders to his officials all over the world to hold a banquet on that evening in towns where there are headquarters. There will be about 350 banquets in America alone and upwards of 30,000 persons are expected to attend.

AMERICAN INSTITUTE OF MINING ENGINEERS

The one hundredth meeting of the American Institute of Mining Engineers, which was organized in Wilkes-Barre in May, 1871, was held at Glen Summit, near Wilkes-Barre, June 6 to 10.

The One Hundredth Meeting, Held at Glen Summit, Pa., June 6 to 10, 1911

A large number of members were present at the meeting, as well as many guests.

On Tuesday morning, the Mineral Spring Breaker of the Lehigh Valley Coal Co., located at Parsons, Pa., about 2½ miles from Wilkes-Barre, was visited. This breaker was completed May 1, 1911, thus replacing a breaker burned in March, 1910. The frame of the breaker is of steel with concrete foundations, and has a capacity of 1,500 tons of prepared coal per day. One million one hundred sixty-nine thousand pounds of steel were used in the construction, and besides being an absolutely modern breaker, it is noted for special loading systems, consisting of traveling belt and a box-car loader. The pockets being central inside the breaker make a radical departure in breaker design. From the Mineral Spring breaker the members and guests were taken by special train to the Hazard Mfg. Co. Here they inspected the method of making wire ropes and copper wire. The visitors saw in the process of manufacture a cable 5,200 feet long and 2½ inches in diameter of cast steel for No. 2 Ashley plane. This, with the exception of the 2¾-inch diameter rope for No. 1 Ashley plane was said to be the longest wire rope manufactured in the United States. The Ashley plane, which is nearly a mile long, hauls the loaded cars from Ashley, just outside of Wilkes-Barre, to the top of the mountain, and is a method followed by the New Jersey Central Railroad of saving a 12-mile haul of coal and freight from the valley to the top of the mountain. Automobiles were provided by the local owners of the Wyoming Valley Country Club, to convey the members and guests to lunch given by the Country Club.

After lunch the visitors were taken to the Vulcan Iron Works, where they saw mining machinery in the process of construction, also a large drum being made for the Ashley plane.

From the Vulcan Iron Works the visitors were taken to the Wyoming Historical and Geological Society, where they were welcomed by Irvin A. Stearns, one of the five original members of the Institute present, and two papers were read, one by S. D. Warriner on the "Anthracite Conciliation Board," the other by John Birkinbine, on progress made since the Institute was founded. From Wilkes-Barre the return was made to Glen Summit by special train, and in the evening a reception was held.

On Thursday the members took a special train over the New Jersey Central Railroad to Mauch Chunk, and then over the Lehigh Coal & Navigation Co.'s road to Lansford. On the way to Lansford the Hauto storage yard of the Lehigh Coal & Navigation Co. was visited and the method of unloading cars and loading them examined. The standard Dodge type of anthracite storage is used at this place. It consists of four 30,000- and two 60,000-ton piles with two more 60,000-ton piles in process of erection, all the machinery electrically driven.

From the storage pile the visitors went by train to Coaldale, where the new No. 9 breaker of the Lehigh Coal & Navigation Co. is situated. The coal bed at this place is between 30 and 50 feet thick, and as there is some rock, and the pitch is steep, everything broken must come out of the rooms. This requires that the plant be made in two sections. First, the head-house, which is made by the Jeffrey Mfg. Co., under contract, and is entirely fireproof; 250 feet distant is the breaker proper, or second section, where the coal is prepared. After examining this plant the members were taken back to Lansford

and furnished an excellent lunch at the club house of the company. After lunch a number of witty speeches were made, one by W. A. Lathrop, president of the company. He was followed by John Birkinbine and Mr. Dodge. The latter was presented with a loving cup made on the spot by Mr. Storrs, of Scranton.

The Lansford briquetting plant, which is practically the pioneer plant in the briquetting of anthracite for domestic use was visited. Besides a briquetting machine, the plant is notable for the pneumatic cleaning methods in use for reducing the amount of ash in the culm before briquetting. The visitors were taken from the briquetting plant to Summit Hill, where a mine fire started in 1859 in a pump house on the Mammoth bed 60 feet thick. Various efforts were made through half a century to extinguish this fire and cut it off from the main workings of the colliery. The final method, which was successfully adopted, cut off the fire by a clay and concrete wall 725 feet long and 12 feet thick, extending from the surface to the bottom of the coal bed. The cost of this closing off was approximately half a million dollars, in addition to over a million previously spent in unsuccessful attempts. The heat from the fire of the old workings could readily be felt and at times smoke could be seen issuing from cracks in the surface.

From the burning mine the visitors walked to the Summit Hill terminal of the Switchback Railroad, which they took for the return trip to Mauch Chunk. This road was built in the very early days of coal operation to convey coal from Summit Hill to slack water navigation on the Lehigh River at Mauch Chunk. It is about 9 miles long and the open cars from Summit Hill to Mauch Chunk run by gravity through the green woods, which added materially to the enjoyment of the trip. The road is now used only for passengers and tourist traffic.

On reaching Mauch Chunk the members took special train over the New Jersey Central back to Glen Summit, where an evening session was held.

Friday morning the members were taken by special train from Glen Summit to South Bethlehem. Here they were welcomed by President Drinker, of Lehigh University, and conveyed by automobiles to the top of the mountain back of the university, where the beautiful Saucon valley spread out before them. They were then conveyed back to the Fritz Laboratory where the 800,000-ton testing machine was examined. This is probably the largest screw testing machine in the world. From the Fritz laboratory they inspected the Coxe metallurgical laboratory and then were led to the college commons where an excellent lunch was served. After lunch they visited the Bethlehem Steel Works, first the Saucon plant, and afterwards the Lehigh plant. At the first-named plant the open-hearth furnaces were first visited, where 60,000 tons of ingots are made per month; next the Grey mill, where 20-inch Bethlehem girder beams weighing 112 pounds per foot are rolled. The capacity of this mill is 1,500 tons per 24 hours. After this the mill yard and fabricating shops were visited, and then the rail mill, where 100-pound rails were being rolled. The capacity of this mill is 1,500 tons in 24 hours. The armor plate department was next investigated, and the 14,000-ton forging press was seen at work forging armor for the Argentina battleships, Morena and Rivadavia, the 7,000-ton bending press rectifying armor for the Argentina battleships was also seen at work. The No. 2 machine shop was next visited. The dimensions of this shop are 1,522 feet long by 185 feet wide, and in it 4-, 6-, 12-, and 14-inch guns were being made. Next the machine shops were visited, and in No. 4 shop 6-inch guns, gun limbers, and caissons for the United States Army were being manufactured. In the No. 6 machine shop large gas engines for the Trenton Iron Co., Trenton, N. J., and the Consolidated Coal Co., of Fairmont, W. Va., were seen in the process of manufacture; also gas-driven blowing engines for the Bethlehem Steel Co., and pumping engines for the cities of Pittsburg and Detroit.

The return was made to Summit Hill on special train over the Lehigh Valley Railroad.

Among those present were the following: Mr. and Mrs. Ayres, Hazleton; Mrs. Ayres, Bound Brook; Hugh Archbald, Scranton; James Archbald, Jr., Pottsville; G. S. Adams, Washington, D. C.; W. Balz, New York; J. T. Beard, Scranton; E. H. Benjamin and Miss Benjamin, Oakland, Cal.; J. Birkinbine, Mr. and Mrs. J. L. W. Birkinbine, Philadelphia; W. H. Blauvelt, Syracuse; H. Boyd, Hokendauqua; J. C. Bridgman, Wilkes-Barre; J. L. and Alexander Bryden, Scranton; D. Bunting, Wilkes-Barre; Mr. Carpenter, New York; Mr. and Mrs. F. Chase, Wilkes-Barre; Mr. and Mrs. E. T. Conner, Scranton; Mr. and Mrs. T. Coryell, Lambertville, N. J.; Eckley B. Coxe, Jr., Drifton, Pa.; W. R. Crane, State College, Pa.; A. B. Crichton, Johnstown, Pa.; J. S. Cunningham, Johnstown, Pa.; Mr. and Mrs. N. H. Darton, Washington, D. C.; H. G. Davis, Kingston; A. F. Derr, Wilkes-Barre; Mr. and Mrs. E. V. D'Invilliers, Philadelphia; J. M. Dodge, Philadelphia; W. F. Dodge, Wilkes-Barre; Mr. and Mrs. H. S. Drinker, South Bethlehem; E. W. Dwight, Philadelphia, Pa.; A. S. Dwight, New York; Mr. and Mrs. L. O. Emmerich, Hazleton, Pa.; C. Enzian, Wilkes-Barre; Mr. and Mrs. T. N. Eynon, and Miss Eynon, Philadelphia, Pa.; E. B. Edgar, Wilkes-Barre; H. T. Firmstone, Germantown; F. S. Foote, Jr., Urbana, Ill.; Mr. and Mrs. R J. Foster, Scranton; B. E. Fernow, Toronto, Can.; F. A. Gleason, Scranton; William Griffith, Pittston; H. R. Gough, Scranton; Mr. Greslam, New York; Mr. Handy, New York; G. T. Haldeman, Wilkes-Barre; Mr. and Mrs. H. R. Hall, Catasauqua; S. H. Hamilton, New York; N. V. Hansell, New York; H. D. Hibbard, Plainfield N. J.; J. M. Hodge, Big Stone Gap, Va.; Mr. and Mrs. L. Holbrook, New York; J. A. Holmes, Washington, D. C.; O. P. Hood, Houghton, Mich.; Mr. and Mrs. F. W. Iredell, New York; A. B. Jessup, Wilkes-Barre, Pa.; R. W. Johnson, Wilkes-Barre, Pa.; W. Kelley, Vulcan, W. Va.; P. S. King, Philadelphia; H. C. Kirchoff, New York; A. C. LaMonte, Scranton; Mr. and Mrs. W. A. Lathrop, Dorranceton; A. F. Law, Scranton; J. S. Lane, Brooklyn; A. B. Ledoux, New York; W. O. Lentz, Mauch Chunk; Mr. and Mrs. L. F. Lentz, Jr., Mauch Chunk; J. J. Lincoln, Elkhorn, W. Va.; Mr. and Mrs. C. P. Linville, State College, Pa.; J. E. Little, Steelton, Pa.; W. H. Loomis, Jeddo; Mr. and Mrs. E. Ludlow, Eccles, W. Va.; Mr. and Mrs. D. A. Lyle, St. David's, Pa.; J. Lilly, Lambertville, N. J.; J. Lloyd, Wilkes-Barre; Mr. and Mrs. F. Wilson and Miss Wilson, Scranton; Mr. Whitaker, Allentown; Mr. and Mrs. S. D. Warriner, Wilkes-Barre; H. S. Webb, Scranton; Mr. and Mrs. W. G. Whilding, Lansford; E. B. Wagner, Wilkes-Barre; Mr. and Mrs. F. E. Zerby, Wilkes-Barre; D. D. Davis, Kingston.

ELECTRICITY IN MINING

*Written for Mines and Minerals, by Walter C. Wagner**

The first practically successful electric mine haulage locomotive was installed in the Erie colliery, 14 miles from Scranton, Pa., in 1889. It had a single motor, operated by a controller at either end. The great cost of plant equipment at that time prevented a saving in the cost per ton mile, but effected an appreciable economy by increasing the output per day.

Views of a Practical Mine Electrician As to the Requirements of Different Machines

Three types of locomotive drives are now in general use: the standard friction drive, the rack-rail drive, and a combination of these. The first can be used on good track up to 7-per-cent. grade. The rack-rail is used for greater pitches than this. The combination finds its place where tracks of both ordinary and steep gradients are met with. The rack-rail is not popular because of the care necessary to maintain a good road bed and a clean one. Rock falls and heaves make track repairs expensive, while the motors in the locomotives, not having their load limited by slipping of the drivers, sometimes undergo severe mechanical stresses and excessive heating and sparking. Either inside or outside wheels are used, depending upon the size and arrangement of motors with respect to gauge of track and width of entry.

Another classification divides locomotives into the standard, the gathering, and the crab type units. The standard, having a draw-bar at either end, travels along entries having both the trolley wire and the bonded rail return. The gathering locomotive is of a standard type having an auxiliary motor-driven drum carrying a reel of insulated wire. This wire is attached by a hook to the trolley, and permits running into rooms or entry extensions having no trolley wire. The track, however, must be of iron with one rail bonded. In damp entries the insulation of the wire on the drum becomes charged and defective and dangerous to handle. The crab locomotive has an auxiliary motor-driven drum carrying a small haulage rope. This rope is paid out by the motorman when the car runner carries it into a room or slant and attaches it to a mine car. The locomotive then draws the car toward it, and at the same time approaches another room in the entry. By the time the car has reached the locomotive, the switcher is again ready to carry the rope to the car in the second room. Slants may be handled very economically by means of a dead rope and a standard locomotive.

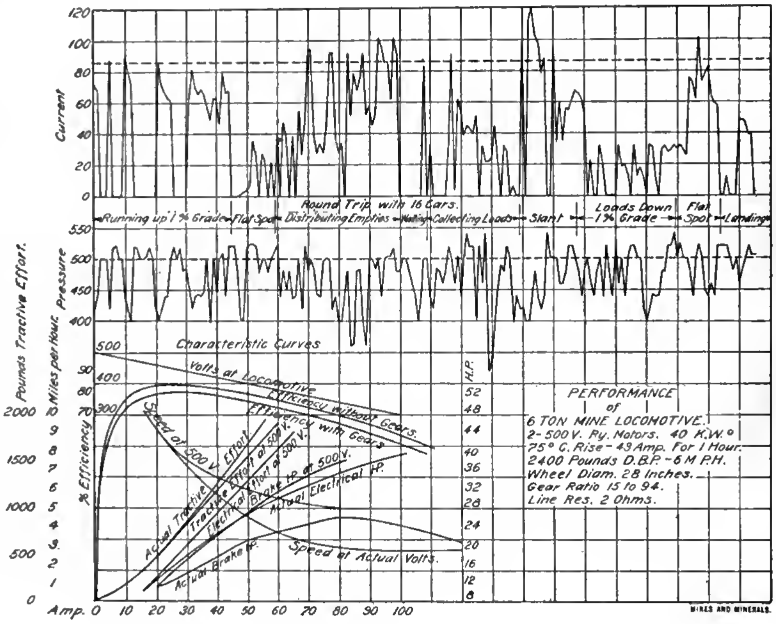


Fig. 1

One to three motors are hung in locomotive frames. They are mounted on the driving axles to permit of vertical movement and make differences of gear meshing impossible. Springs support the other end and lessen the vibration. They may be tandem, outside or inside hung. The tandem is practically standard, the motors hanging on the same side of their respective axles. This permits of a compact and satisfactory arrangement of motors, brake mechanism, and resistances. The outside hung motors are on opposite sides of their respective axles, giving the locomotive a very short wheel base for tracks having sharp curves, but making it unsuitable for high speeds. On larger units the motorman's position is in the center of the locomotive. The inside hung motors have their noses together and have a long wheel base. This type is most satisfactory for high speed service. It is well suited for double-end control, but makes inspection and repairs sometimes difficult; the available space being utilized by the motors, gears, and resistances.

The alternating-current single-phase motor has not as yet entered this field, because of the greater size and cost per horsepower output. This would in many cases, however, be compensated by the increased economy in power transmission.

The gear ratio is somewhat higher than that in the standard outside service, running from an average of 4.6 to 6.3 or more. This, of course, implies a smaller motor, a very important item, a strong starting torque, and a higher running speed. In mine entries the grade is about 1 per cent. in favor of the loads, thus permitting high-speed coasting and a consequently shorter time per trip. This coasting, however, is very hard on the motors and gears. Some practical method of throwing the gears out of mesh would also increase the braking effort of the locomotive. The resistances are generally of the flat iron ribbon type separated by mica or asbestos. The cost of resistance maintenance is excessive, as their current carrying capacity is not yet what it should be. The cast grid type is very efficient on heavy runs where there is a very good track but a great amount of switching.

The size, weight, and speed of locomotives are determined by local conditions. In ordinary mines having small beds of coal and light track and long entries, a locomotive heavier than 6 tons or faster than 6 miles per hour is not advisable. The size of motors and gear ratio, compared with the weight, should be such as to allow a locomotive to put her nose against a rib and grind away for half an hour without a burn-out.†

Series, parallel, and series-parallel controllers are used at one or both ends, and sometimes one controller operates two locomotives. One type of controller is arranged to connect the motors together when the controller handle is on the off position. Any slight difference in speed will cause one motor to act as a generator and tend to drive the other in an opposite direction, thus forming an electric brake. This attachment is not advisable, as it means an almost continuous service, and a consequently greater rise in temperature in the motors. For extreme emergencies the reverse handle may be thrown over and both sets of drivers reversed.

The various forms of good controllers make use of a magnetic blow-out by which the arcing is reduced to a minimum, and use pure copper segments and fingers, or those tipped with copper at the arcing points. Immersing a complete controller in transformer oil was tried. The wear and arcing was greatly reduced but it proved to be very dirty and made inspection

* N. W. Improvement Co., Tacoma, Wash.

† This should be a manufacturers' test, not an operator's.

difficult. Reversal of direction is generally accomplished by reversal of current through the armature, the field being on the ground side. With the severe service met with in mines, an electrical protective device on the locomotive would seem necessary. In practice, however, a circuit breaker or device in a screened fireproof chamber on the feed-line gives more satisfactory results.

It is customary for manufacturers to use but two 250-volt incandescent lamps, in series, for head lights. As the destruction of one lamp means the destruction of both, the use of an additional series lamp of half candlepower and half voltage has been tried. This results in a longer life to the lamps, a good illumination, and the burning out of only one of them at a time. Although the motors are enclosed, most of the troubles result from dirt and moisture. Armature bearings giving good service will, because of dirt, sometimes wear in a few days enough to allow the armature to rub on the pole pieces, tearing off band wires, and perhaps destroying brush holders and field coils as well. Severe sparking due to high mica on commutators has been cured by cutting down the mica about $\frac{1}{8}$ of an inch with broken hack saw blades and water. Mine moisture is splendidly adapted for corrosive action and finds its way into any winding or connection not protected. Coils that have been partly impregnated are more dangerous than coils without treatment. The moisture in the latter often is evaporated, but the former seems to hold it and break down more easily. This makes a regular and careful inspection and testing necessary. Frequent switching, bucking cars along with locked bumpers, running trips over bad tracks and road beds, and using a locomotive beyond the limit of its capacity, mean a service many times more severe than is met with outside. Manufacturers are now realizing this, and equip the same weight locomotives with motors of greater horsepower. Many other points could be remedied if the manufacturers made an effort to keep in closer touch with mine-operating conditions.

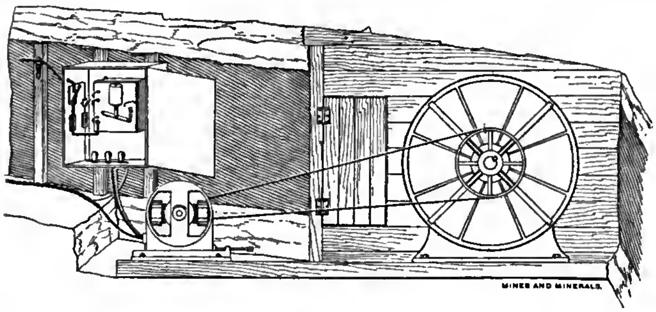

FIG. 2. BOOSTER FAN

On very heavy grades, consideration must be taken of the decreased tractive effort of the locomotive, as well as that necessary to drive itself. In some cases where the locomotive drawbar is somewhat higher than that of the car, a tilting action of the locomotive frame lightens the load on a motor farther from the coupling and increases the load on the other motor correspondingly, causing frequent burn-outs. Then too, when series control is used alone, one motor may cause its drivers to slip; the counter electromotive force of this motor preventing a sufficient current flow to enable the other motor to move under a heavy load.

A typical round-trip performance of a mine locomotive is indicated by curves shown in Fig. 1. This is a 6-ton locomotive with two tandem motors, rated at 6 miles per hour, with an electrical input of 40 kilowatts on a drawbar pull of 2,400 pounds, or 400 pounds per ton.

The starting drawbar pull, or maximum tractive effort, is approximately 150 per cent. of that of 3,600 pounds, with a current consumption of 500 volts of 115 amperes. The ragged current and voltage curves are noted to occur during the whole of the round trip. The current serves also as a direct measure of the torque, which can be computed from the actual characteristic curves.

As the entry often runs on the strike of the coal, one side of the track is ballasted and the other rests on bed rock. This means a poor, uneven track, sometimes dirty from loose coal falling off cars or from rock falls. Then, too, wet spots and small increases of grades are often met with, requiring frequent sanding. Although the couplings are long, the grade keeps them tight and requires a greater accelerative torque than when running on the level. As this entry is one of four in a mine about 2 miles from the power station, and each of them has a locomotive, besides using four electric booster fans and an electric hoist, no further explanation is necessary of the apparently inconsistent variation of voltage. It is typical of mine service. The generators at the power house are not overcompounded, and there is therefore no compensation for line loss. This results in this particular case in quite a drop of pressure when the electric locomotive is pulling heavily; consequently the characteristics obtained at 500 volts can not very well be used for correct calculation at 100 amperes consumption. The changes in such characteristics due to two ohms drop in the feeder line and return are sketched in roughly. The decrease in electrical and brake horsepower is very apparent, resulting in great loss of speed at heavy loads, but increasing the tractive effort at this lower speed. It is interesting to note the enormous difference of performance between an ordinary day trip such as is shown here, and one with very cold weather outside. The empties coming from the outside run with great difficulty because of frozen boxings, and often require more than a 50-per-cent. increase in torque; by the time they are loaded, however, the mine temperature has thawed them sufficiently to make the outgoing trip a fairly normal one.

Where the inertia of the trip of cars at starting, or increased resistance due to a dirty track, causes the locomotive to pull heavily and run slowly, the effect of a long feed line causing an appreciable voltage drop at the locomotive is of interest. The drop of course is proportional to the current consumption.

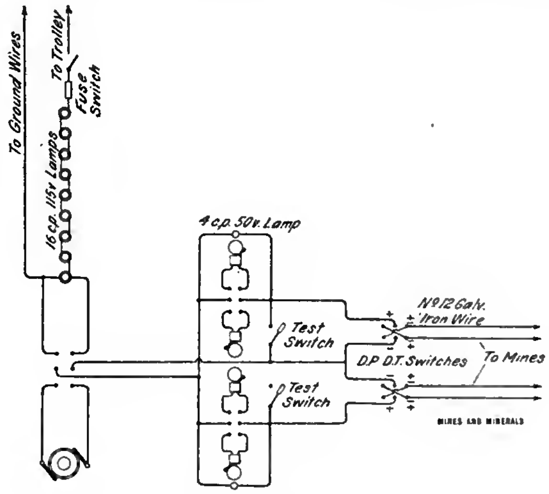

FIG. 3. SIGNALING ARRANGEMENT

The motor torque is proportional to the current only, and is independent of the impressed electromotive force. With a heavy pull, the motors' speed need not be so great; as an increase in current flow means less speed for the necessary current electromotive force. As the applied electromotive force decreases (due to line loss) and the current electromotive force increases with the greater current flow, the torque, and therefore the current, does not increase as in the case of constant applied voltage. There is therefore less danger of overloading the motors. As the tractive effort also is higher at lower speeds, such line resistance allows of larger trips to be started by a certain weight locomotive without an excessive output at

the power house. As the trip resistance is decreased after starting, the speed rises with the decreased current and increased applied electromotive force making up for time lost on the heavy pull when starting.

Another advantage of a long feed-line is decreased harmfulness of short circuits. A short circuit on this 2-mile line will blow the circuit breaker without causing a violent flashing of the generator brushes or excessive arcing at the contacts of the circuit breaker, since the current cannot exceed 300 amperes.

This excessive electromotive force variation is exceedingly hard on the shunt motors driving ventilating fans, and is the cause of a great portion of the trouble with them.

These motors are usually belted to the generating units, although in some cases they are direct driven. A belt drive permits of easy inspection and cleaning. The motor is less dirty and can be replaced by another motor with different speed by changing the size of the pulley. Blasting, causing a sudden stoppage of the fan, simply means the slipping of a belt having guides and not a burn-out. The motors may be of high speed and have a correspondingly less weight and volume to a given horsepower.

In places where a burn-out or stoppage of one motor would be dangerous, a relay is installed with its pulley just above or below the working motor, thus allowing the use of the same belt by either machine, with a minimum of time for changing over.

For 5 and 10 horsepower motors it has been found advisable to place a series winding over the shunt fields, heavily over-compounding them. This does away with the starting box and its attendant troubles. The present type of automatic starting devices are not sufficiently protected to withstand the moist mine atmosphere and the attendant electrolysis.

Mine fans are placed at the mine openings and also along air-courses inside. The former, often termed ventilators, usually handle the entire air flow of a mine. The latter, called boosters, are placed in the air-courses to assist and control the flow of air through the workings.

Electrically driven fans are of either the centrifugal or disk type. The centrifugal, as the name implies, is built somewhat like a waterwheel, having paddles or blades parallel to the axle of the shaft and forcing out the air at right angles to it. This type is in general use at mine openings. It is not efficient in booster service, as it drives the air against the rib, requiring it to make two turns of 90 degrees, and creates a whirl before resuming its natural flow along the air-course.

The disk fan, having radial blades set at an angle to the axis of the shaft, is better adapted for general inside mine ventilation, as the air is driven parallel to the rib. It is built in smaller sizes and used in smaller workings or in booster service. A typical booster fan installation, one of a series along the air-courses of an extensive mine, is shown in Fig. 2.

The fan, with its surrounding air-tight stopping, is placed directly across the air-course. The air is being driven toward the observer, as the door is built to swing in this direction. With the fan in operation the freely swinging door is closed by the excess pressure on this side of the stopping. If for any reason the fan should cease to operate, the flow of air, due to the other fans, would open this door. This open area, together with the spaces between the fan blades, guarantees a continuous flow of air through the air-course.

The motor is placed as far from the fan as possible to give a good drive without a tight belt. Sometimes a small room is cut out of the rib, or an old slant is utilized for this purpose. The feed-line is shown coming in on props set against the rib. The ground return is often an old steel haulage rope running along the entry to a main copper return outside. The automatic starter is shown in an asbestos-lined wood box having a sheet-iron door. The incandescent lamps keep the starter, fuses, and switches in a dry insulated condition. A change in wiring has been made since the time of this sketch, bringing the high or trolley wire through the main switch and fuse directly to the line terminal of the motor. This brings all the live parts of the starter to a ground potential when running, making it safer for the attendants.

There is a maximum demand in ventilation as well as in pumping. As the mine air is at nearly a uniform temperature the whole year, the outside temperature variation either aids or retards the flow of air. If the intake is below the level of the discharge the warmer weather will resist the flow; if colder, the weather assists the fans, and in some smaller mines makes them unnecessary. In some cases an economy is effected by a reversal of the fans with a decided change of temperature.

Signaling service in mining work must be absolutely reliable in the face of the most adverse conditions. Primary batteries are used where no other electric power is available. They require frequent inspection and renewals, but give good results where the bells are not in continuous service. On long inclines where no stops are made between terminals magnetos or telephones are used. This is not good practice, as the trip rider has no means of signaling in case of trouble. With electric power at hand, the arrangement shown in Fig. 3 has proven to be very satisfactory. A 1.5 horsepower 50-volt generator is driven from the shaft of a ventilating fan. A bank of 16-candlepower 115-volt lamps in series is used as a relay, the low voltage power being taken from the ground lamp of the series. It has been found advisable to replace this with two lamps in multiple to insure against the breaking of a filament. Each slope has a separate signal board in front of the engineer, upon which are mounted the set of two bells, two switches, and a 50-volt signal lamp. The single-pole switch is used to test the bells. The double-pole, double-throw switch allows either bell to be used. The lamp flashes up whenever a signal is given insuring absolute reliability. It is also a good indicator of the condition of the line in the case of short circuits and grounds on the mine wires. The double-throw double-pole switches leading to the iron signal wire are used in case one wire grounds in the mine and rings the bell continuously. Throwing over the switch connects the clear wire to the other side and keeps the signals working until the mine stops for the day and allows repairs to be made. In some installations a battery is placed as a relay for the lamp bank power supply. The direct-current vibrating bell has one weak point, the contact. In ordinary mining service the contacts are allowed to be eaten away and then trouble due to sticking or poor contact results. The continued vibration, together with a flow of current in one direction in the coils, often produces a polarized core with an appreciable residual magnetism, causing the armature to stick to the core. Breakage of the spring holding the vibrating contact is very common in hard service. A cure for these coils would be the use of a small alternating-current generator in the place of the direct-current one and the use of alternating-current ringers. The emergency relay would be from the direct-current supply with direct-current bells.

It is necessary in handling a large field to keep in intimate touch with all phases of the work, its performance with respect to thoroughness and efficiency, and the cost of operation. The group of reports and cards needs but little comment. The Motor Report is very useful; the date of trouble and the date of repairs, together with the time required, give a complete knowledge of daily performance. The Daily Report Electrical Department gives a summary of costs divided according to the classes of work. In this way one can observe the proportionate amount of attention given by each electrician in his mine to each division of work.

The Daily Station Report shows graphically the run of the generating units for the 24 hours. Current and voltage readings, together with their maximum values, give an accurate distribution for power charges against the different mines.

The Electric Light Department sheet gives an idea of the system used to handle the light revenue account. When the

work is completed the material list is filled out together with the amount of time. This is then approved by the electrical engineer and turned in to the accountant's office for collection.

A card-index system is kept of the different units. This enables duplicate repair parts to be obtained without going into the mines, and also facilitates more economical arrangements of the units. Tests of load voltage, etc., are placed on the back of the card.

Cost data are kept in a similar manner, each job being noted as completed.

A NEW BREATHING APPARATUS

Written for Mines and Minerals

Since the introduction of recovery apparatus in the United States there has been a decided feeling among mining men that something less cumbersome, less complicated, and more dependable was needed. From the outset it was evident that to do effective work the operator must not be incumbered by weight or be compelled to breathe rarefied air. Further, that he must not be troubled or made anxious because his life depended upon a system of complicated reducing valves, pressure gauges, high-pressure hose, or other intricate parts liable to become deranged.

Seeing the weaknesses in the first recovery apparatus, one was invented, which, however, did not comply with all the requirements, but being confident that he had the right principle for the foundation of a satisfactory rescue apparatus, the inventor persevered until he produced the apparatus here described. It is in two styles, the larger called the Dreadnaught as shown in Figs. 3 and 4 and a lighter "Emergency" apparatus shown in Figs. 1 and 2. The first demonstration convinced the writer that the "Emergency" form was a success and the second demonstration, before the district superintendents and the mining engineers of the Delaware, Lackawanna & Western Railroad Co., further convinced him that both were successes.

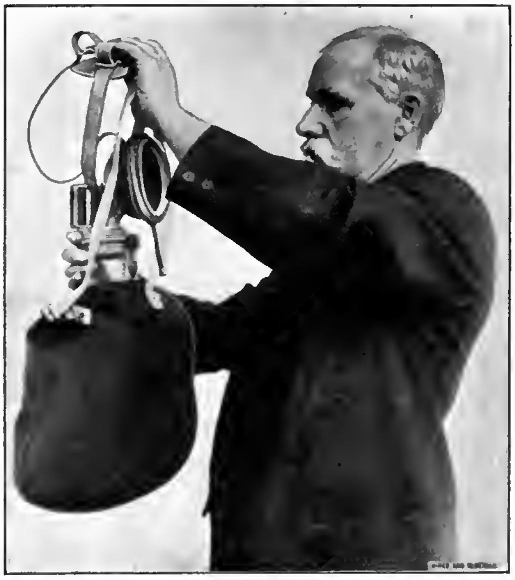

Fig. 1

Those present saw an operator equipped with a Dreadnaught enter a room filled with ammonia fumes, and then one of their own number enter with the Emergency apparatus and remain 18 minutes. It is not probable that a man unprotected could have remained 2 minutes in such an atmosphere, yet the Dreadnaught operator remained three-quarters of an hour and lifted iron billets about the room without inconvenience. There is no question but that he could have stayed there over an hour longer, but 15 minutes in such an atmosphere was more than was necessary to convince the observers of the value of the apparatus.

The Emergency apparatus weighs 4 pounds when charged and is carried on the head and neck in such a way as to cause no discomfort, and at the same time allows the use of both hands. It carries a charge of oxodon, a chemical oxygen compound manufactured by the electrolytic process, which releases oxygen gas and removes the carbon dioxide from the exhalation. One charge in this little apparatus is sufficient to sustain a man walking fast 1 hour, and owing to the light weight of the apparatus several can be carried at one time into the mine in case of an explosion or fire and dealt out to any men who have been walled off by gas or smoke. As the face of the operator is not entirely covered he is in no danger of becoming overheated, as is possible with the wearer of a helmet. One user of the helmet apparatus stated that after 20 minutes the operators lose their efficiency when working, for which reason, in fire fighting, shifts are reduced to 20 minutes each. The Emergency would permit men to retain their efficiency for 1-hour shifts, if necessary. The oxodon, which is hermetically sealed in cans, will remain active a long time, provided no moisture reaches it, thus making it practical to store several Emergency apparatuses at strategic places in mines where they could be readily reached by miners in case of disaster.

Fig. 2

The Dreadnaught is a much larger apparatus and weighs 20 pounds when charged with oxodon in quantities to last 3 hours. This apparatus has features which are worthy of consideration. In the first place the weight is distributed on the back and chest, making it self-contained, as the machinist says. The oxodon is carried in a tight bag in front while the water necessary for the generation of oxygen is carried in a box on the back. When the charge is placed in the bag and the water turned on, the chemical immediately generates oxygen. A mask which covers the nose and mouth is arranged to fit any face without adjustment. At the same time it is held in place by straps so that it cannot readily come off. This mask is connected with two rubber tubes leading into the generating bag, and since the liberation of oxygen depends on the moisture admitted to the chemical, increased respiration insures increased supply of oxygen to meet the demand of the lungs.

The advantages of the Dreadnaught are as follows:

The weight is 20 pounds, less than one-half the weight of the apparatus used by the Bureau of Mines, and is about equally distributed front and back, while in other types the weight is almost all suspended on the back. There are no high-pressure cylinders, reducing valves, pressure gauges, high-pressure hose, or other intricate parts, thereby reducing the chances of the apparatus getting out of order while in service. There is no expensive oxygen pump to transport and keep in order, neither are oxygen tanks required to be carried with the apparatus. The Dreadnaught is easily portable. One can carry an apparatus and enough cartridges for 12 hours' work in a case, and so save valuable time, expressage, and delays at critical times. The capacity of one charge is 3 hours, and this

is about 1 hour in excess of the best other apparatus. The cost of operation is low—about 85 cents per hour. Owing to the simplicity of the apparatus less training is needed for successful operation and the operator can always determine the condition of his charge without the aid of a gauge. In fact, with a watch he is safer alone than are two men with pressure gauges on their backs.

Fig. 3

Another feature which adds materially to the usefulness of this apparatus is that by adding a 6½-pound storage battery to the back piece a strong electric light may be had. This light is attached to the front of the device, but is readily detached and by means of flexible wires can be used as a hand light as shown in Fig. 4. Although the light increases the weight of the Dreadnaught to 26½ pounds, it is a most desirable acquisition, because the operator would carry an electric light probably weighing as much as 5½ pounds in his hands, while in this case he has both hands free, and a strong light always thrown ahead of him.

Another good feature in this new apparatus is that the heat due to having the neck and face covered by the helmet is greatly lessened by the mask used, and this will be appreciated. The cost of the apparatus is comparatively low, and duplicate parts are exceedingly cheap compared with other apparatus, besides there are few parts that get out of order.

The makers are the Servus Rescue Equipment Co., of Newark, N. J.

METHOD OF INSTALLING FANS

Written for Mines and Minerals, by Thos. W. Fitch, Jr., and Jay R. McColl, M. E.

The most general practice in the use of large fans is to install concrete or brick foundations up to the center line of the fan. The shaft carrying the fan wheel is usually supported on bridges or cast-iron standards at the inlet circle, and steel housing is provided above the center line of the fan; also steel stack. The drifts at the side of the fan with roofs over them are usually built of brick or concrete. In some cases, fan manufacturers build these side drifts of steel.

The use of self-contained full-housed steel fans has been rare heretofore, but with the introduction of the "Sirocco" fan they have come into more general use on account of the smaller diameters used. With this fan the ratio of inlet diameter to the diameter of the fan is 80 per cent., whereas with previous types 50 per cent. to 60 per cent. was the maximum.

Another prominent feature introduced with the "Sirocco" fan is that the clear area of inlet exceeds 90 per cent. of the calculated area, whereas with fans having arms, spiders, tee or angle irons on the backs of the vanes to form obstructions in the inlet, the clear area of inlet is reduced from 60 per cent. to 80 per cent. of the calculated area. From this it will be noted that with the same area of inlet as fans of previous types, the diameters of "Sirocco" fans are very much less, allowing of the use of full steel-plate housings with far less vibration when in operation, and of greater stability, due to the lesser distance of the bearings above the foundation.

The general method of driving mine fans is by direct-connected steam engines, and this has had a great influence in limiting the speed of fans in use. In the anthracite fields of Pennsylvania it has been usual to limit the speed to 75 to 90 revolutions per minute. These extremely slow speeds are not as necessary with modern methods of fan manufacture as was formerly the case, and it is obvious that old style unwieldy fans, revolving at 70 to 90 revolutions per minute on partly true shafts are not and cannot be mechanically equal to smaller and less weighty fans running about 150 revolutions per minute.

In the bituminous coal fields, direct-connected units are operated at from 125 to 175 revolutions per minute, depending upon the type of engine and the size of the fan. As mine operators have generally found that there is more or less trouble to be had with belts, there is a very strong prejudice against indirect drives. However, they will come into more general use with the tendency to use smaller high-speed fans and with the use of electric motors for driving fans. The particular advantage in steam-driven fans is that the fan can be run 24 hours a day, with Sundays and holidays included, without regard to the operation of any other apparatus, but if the fan is electrically driven it becomes necessary to run the generator continuously, which is not always possible or desirable.

Gear drives have been found inapplicable to fan drives, because owing to shot firing in the mine and the opening and closing of doors, sudden slight changes in the speed of the fan take place, causing heavy backlashes. In England and Germany where a great many high-speed fans are installed, the popular drive is the English system of ropes. That is, a number of separate ropes. Fans direct-connected to motors have not met with large success in this country up to the present time, largely for the reason that the size of the motor required is too great. With many types of fans, if sufficient area of inlet is provided, it makes the fan of such large diameter that it cannot run at a very high number of revolutions, and if a direct-connected motor is used it must be very large to develop the necessary power at the slow speed. In this connection, the

Fig. 4

"Sirocco" fan has an advantage, as with the same area of inlet the fan is much smaller in diameter and can, therefore, run at a much higher speed. In both the case of direct-connected engines and direct-connected motors, it is to be noted that there is a great advantage in their favor, viz., the loss of power in an indirect drive would ordinarily amount to about 10 per cent. of the power delivered to the fan; and the possibility of trouble with an indirect drive is eliminated by direct connecting.

THE NEW ILLINOIS MINING LAW

Written for Mines and Minerals

The legislature of Illinois at the session recently adjourned, passed several mining bills changing the mining law of the state that has been in force for a number of years.

Practically the Law Recommended by the Mining Investigation Commission

These bills were presented to the legislature as the result of the work of the Mining Investigation Commission authorized by the Forty-Sixth General Assembly. This commission was composed of three coal operators, three coal miners and three disinterested persons who had no connection with the coal industry of the state. The laws as passed by the legislature are practically those recommended by the commission, with two exceptions, which have to do with the inspection service rather than directly with the safety features of the law. The report of the commission recommended an increase of salary for the State Mine Inspectors from $1,800 to $3,000. This was not allowed. The report also suggested the substitution of deputy inspectors instead of county inspectors but this was not agreed to by the legislature, and Illinois still has the dual system of inspection consisting of state inspectors appointed by the governor, and county inspectors appointed by the county boards.

The essential features of the new law are the following: The general direction of mining matters is placed in the hands of the State Mining Board, consisting of two practicing coal miners, one practicing coal-mining hoisting engineer, and two coal operators. Under the previous law the board was similarly constituted, but it was mainly a board for examining applicants for state certificates. The new law gives the board specific authority and direct supervision over the inspection service and the mining practice of the state for a period of two years, the president must be a coal operator and the secretary a coal miner. The compensation of the members of the board is five ($5) dollars per day and the number of days of service per annum is limited to 100. In addition to the supervision of mining matters, the gathering of statistics and the publication of a coal report is placed under the board. A chief clerk to the board at a salary of $2,000 per annum is provided.

The requirements in regard to qualifications of and examinations for inspectors, mine managers, mine examiners and hoisting engineers are practically the same as in the previous law, excepting that a knowledge of rescue work and first-aid work is required upon the part of mine inspectors and mine managers. It is also a new requirement that all examination papers shall be kept on file, and the applicant may secure a copy of his paper within a reasonable time by paying a suitable copy fee. The requirements for the employment of certificated managers, examiners, and hoisting engineers, are essentially the same as under the old law. The number of mine inspectors has been increased from 10 to 12 and provision made so that inspectors shall have a better allowance for expenses than has been heretofore possible. This is a much-needed improvement, as heretofore not only have the salaries been too small but the allowance for expenses has been so meager that it was frequently exhausted before the end of the fiscal year and any subsequent inspection had to be done at the personal expense of the inspector. Definite provision has also been incorporated in the law authorizing and directing the State Mining Board to furnish each inspector with the necessary instruments needed in carrying out his work.

Every mine in which marsh gas has been detected in quantities, which in the judgment of the mining board is dangerous, must be examined at least once in six months by the state inspector. The state board may require the state inspectors to examine any and all mines when they deem it necessary. Inspectors are required to measure the air in the last cross-cut in each pair of entries and in the last room of each division in longwall mines and must supply a written report of each inspection to the State Mining Board.

As heretofore, the inspectors continue to be sealers of weights, although it seems to be an unnecessary burden and one that is in no way connected with the safety of the miners.

The requirements in regard to maps are essentially as heretofore, excepting that the data on maps must now include the location and depth of all holes drilled for oil, gas, or water, that penetrate a workable coal seam. In order that the engineer of the coal company may have the data necessary for carrying out this provision, a separate law was enacted requiring the driller of every such hole to file with the county clerk of the county in which the hole is drilled a description and map showing the location of every such hole, which map and description become a part of the title record of the tract of land.

Mines to be abandoned or indefinitely closed are required to be mapped before such abandonment. The state inspector of mines may order additional maps to those required by law, if he has any reason to believe that the maps furnished him are inaccurate he may have another map made at the expense of the operator.

The new law has definitely placed the operation of shaft sinking under the inspection service and requires a safe and substantial structure to support the head-sheaves placed at a height of not less than 15 feet above the landing place.

A platform must also be arranged to prevent material from falling into the shaft. No material can be hoisted from the bottom, when men are in the shaft, excepting in a bucket or on a cage. Provision is made for properly attaching a rope to the engine drum, and for providing the engine with a brake. Not more than four persons can be lowered or hoisted in the bucket at one time and it is unlawful to ride on a loaded bucket. In sinking, all shots must be fired by electricity and the hoisting engineer must be a certificated man.

The second shaft, commonly known as the escapement shaft, shall be not less than 500 feet nor more than 2,000 feet from the hoisting shaft, excepting that in mines employing 10 men or less this distance may not be less than 250 feet. The escapement shaft, if equipped with a cage for hoisting men, must conform to all of the requirements of the hoisting shaft in reference to the hoisting and lowering of men.

Several material changes have been made in the regulations about the shaft bottom and provision is now made for a passageway from one side of the cage to the other, "free from obstruction and dry as possible and not less than 3 feet wide and for the use of men only; animals or cars shall not be taken through such passageway while the men are passing or desirous of passing through such passageway."

A refuge place or places for men coming out at the close of the day's work shall be provided off the main bottom, at such place or places and of such size as approved by the mine inspector. These places shall be not more than 400 feet from the hoisting shaft.

No inflammable structure can be erected or reerected on the surface within 100 feet of any hoisting shaft or escapement shaft excepting in mines employing 10 men or less, and no oil or similarly inflammable materials can be stored within 100 feet of any hoisting or escapement shaft or within a mine.

The regulations in regard to safety lamps have been considerably extended and at every mine in the state there must now be kept at least two safety lamps and as many more as may be required by the state mine inspector. The regulations for the use of the safety lamps are also quite stringent. No man is allowed to use one until he has shown that he understands the proper use thereof and the danger of tampering with it. In any mine where locked safety lamps are used it is made a misdemeanor for an unauthorized person to have in his possession any means for unlocking a safety lamp or any matches or other means of producing a fire.

To reduce the danger from excessive shooting in closed

places the following provision is made: "When undercut or sheared, the entry, cross-cut and room neck may be advanced concurrently, but not more than one cutting shall be shot in the room neck until the cross-cut is finished; and after the entry has advanced 15 feet beyond the location of the new cross-cut, only one shot shall be fired in the entry to two in either or both the cross-cut and room neck at the same shooting time.

"When not undercut or sheared, the entry and cross-cut may be advanced concurrently, but no room shall be opened in advance of the last open cross-cut, and after the entry has advanced 15 feet beyond the location of a new cross-cut only one shot shall be fired in the entry to two in the cross-cut at the same shooting time.

"Not more than three shots shall be exploded at one shooting time ahead of the last open cross-cut."

Provision is made for staggering the cross-cuts between rooms.

The inspector is required if he finds men working without the proper amount of air to notify the mine manager to increase the amount of air, and in case of the refusal of the manager to act properly and in all cases where men are endangered by such lack of air, the inspector shall at once order the men affected out of the mine.

Provision is made for keeping the roads clean so as not to endanger the drivers in jumping off their trips.

The regulations in regard to illuminating oils are completely changed and all illuminating oils are required to conform to specifications provided by the mining board. All oil must be stamped or branded upon the original package, showing that it has been tested and found to conform to the specifications as prescribed by the mining board. Any person selling or offering for sale oil not complying with the specifications, and any owner, operator or employe, who knowingly uses in a mine or who knowingly permits to be used any oil forbidden by the act, is guilty of a misdemeanor. The state mine inspectors are given authority to sample all oil used for illuminating purposes or kept on sale for use and it is made their duty to send to the State Mining Board samples of any oil that they have reason to suspect does not conform to these standards or specifications.

The amount of powder kept by any one workman is increased from 25 to 35 pounds. The reason of the change being made is that according to the old law, if a miner had a part of a keg of powder left at night, or not enough to run him through the following day, he was prohibited from bringing in a new keg until after the part of the keg has been used.

The following regulations in regard to dead holes have been incorporated:

"No person shall drill or shoot a dead hole as hereinafter defined. A 'dead hole' is a hole where the width of the shot at the point measured at right angles to the line of the hole is so great that the heel is not of sufficient strength to at least balance the resistance at the point. The heel means that part of the shot which lies outside of the powder.

"In solid shooting, the width of the shot at the point, in seams of coal 6 feet or less in height, shall not be greater than the height of the coal, and in seams of coal more than 6 feet in thickness the width of the shot at the point shall, in no case, be more than 6 feet.

"In undercut coal, no hole shall be drilled 'on the solid' for any part of its length."

Mixed shots are prohibited. Holes are required to be tamped full and no coal dust or inflammable material or any material that can create a spark can be used for tamping Missed shots cannot be withdrawn excepting with the use of copper tipped or wooden tools.

The duties of the mine manager, mine examiner, hoisting engineer, are essentially the same as in the previous law, but the wording has been changed so as to be specific, and an effort has been made to avoid ambiguity so that duties cannot be shirked through a lack of definite provisions in the law.

The special rules have been made somewhat more stringent. It has been made a misdemeanor to enter or work in or about a mine or mining building, tracks or machinery connected therewith, while under the influence of intoxicants.

A miner is required to sound and examine the roof of his working place before commencing work, and if he finds loose rock or other dangerous conditions he is forbidden to work in such room under such conditions excepting he make the room safe. No one is allowed to enter or leave a mine without indicating the fact of entering or leaving by some suitable checking system. It is made a misdemeanor to change or alter in any way any car check.

Provision is made for keeping bore holes in advance when abandoned workings are approached. In case there is a map of the old workings, bore holes shall be kept within 50 feet of the old works, such bore holes being 10 feet in depth, one being in the face and one in each rib. The advance working shall not be more than 20 feet wide. If there is no map of the old workings, bore holes will be maintained from the time the new workings reach the point within 100 feet of where the old workings are supposed to be.

By separate act the use of powder has been regulated and the following specifications have been provided for black powder:

"(*a*) It shall have a specific gravity of not less than 1.74 nor more than 1.90.

"(*b*) It shall have a moisture content of not to exceed 1 per cent. at the time when shipped by the manufacturer or his agent.

"(*c*) Said powder shall be sold for use in coal mines only in seven sizes of granulation to be determined as follows:

"CCC shall be powder which shall pass through a screen having round-hole perforations of $\frac{40}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{32}{64}$ of an inch in diameter.

"CC shall be powder which shall pass through a screen having round-hole perforations of $\frac{36}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{24}{64}$ of an inch in diameter.

"C shall be powder which shall pass through a screen having round-hole perforations of $\frac{27}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{18}{64}$ of an inch in diameter.

"F shall be powder which shall pass through a screen having round-hole perforations of $\frac{20}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{12}{64}$ of an inch in diameter.

"FF shall be powder which shall pass through a screen having round-hole perforations of $\frac{14}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{7}{64}$ of an inch in diameter.

"FFF shall be powder which shall pass through a screen having round-hole perforations of $\frac{9}{64}$ of an inch in diameter and remain on a screen having round-hole perforations $\frac{1}{64}$ of an inch in diameter.

"FFFF shall be powder which shall pass through a screen having round-hole perforations of $\frac{5}{64}$ of an inch in diameter and remain on a screen having round-hole perforations of $\frac{2}{64}$ of an inch in diameter.

"In testing powder for size of granulation as herein required, it shall be permissible for a given size to contain not to exceed $7\frac{1}{2}$ per cent. of weight of grains of the size next larger and $7\frac{1}{2}$ by weight of grains of the size next smaller."

All black powder must have plainly stamped on the case the letters showing the sizes of granulation as given above. Failure to conform with these requirements is made a misdemeanor punishable by a fine of not less than $100, or imprisonment for 90 days or both. The state inspector is authorized to sample blasting powder for granulation in conformity with

the sizes given above, and for other tests he is authorized to sample powder and send the same to the State Mining Board.

A separate act prohibits the drilling of oil or gas wells nearer than 250 feet to any opening of a mine used as a mine's egress for persons employed therein or as an air-shaft. As noted above, it is incumbent on the driller of the oil or gas well to file a record of the depth in the county clerk's office so that it may become a part of the title of that property.

Before the casing shall be drawn from any well the hole must be securely stopped or blocked.

The act requiring fire-fighting equipment, passed by the special session of the legislature which convened after the Cherry disaster, has been amended so as to do away with the gongs near the face of the workings. The fire-fighting equipment required of the small mines has also been reduced by eliminating the requirements for chemical fire-fighting extinguishers in mines employing less than 10 men. The provision in regard to alarm gongs has been changed, since it seems to be the opinion of both operators and miners that such gongs are objectionable and are probably causes of panic rather than an efficient means of warning. To increase the means for warning, however, additional telephones are now required.

The law in regard to the mine-rescue stations remains practically unchanged excepting with a few verbal amendments to permit the commission to more efficiently operate the rescue cars which were not provided in the original act of incorporation. The recommendation of the Rescue Commission for increased salary for the assistants at the stations was not agreed to by the legislature. An appropriation of $30,000 per annum was made for the support of the stations.

A bill authorizing the University of Illinois to establish miners' and mechanics' institutes throughout the state was passed but will not be operative because no money was appropriated to carry out the provisions of the act. An act was also passed continuing the Mining Investigation Commission, or rather providing for the appointment of another commission along the lines identical with those upon which the previous commission acted, the previous commission having gone out of existence when it filed its report to the governor and legislature.

In the appropriations for the University of Illinois, the allowance for maintenance of the mining department given by the previous session of the legislature was doubled and is now $7,500 per annum. An item of $5,000 per annum was appropriated calling for cooperative investigations between the United States Bureau of Mines, the Illinois Geological Survey, and the Department of Mining Engineering. An appropriation of $25,000 was also made for equipment for the Department of Mining Engineering, and an appropriation of $200,000 was made for a new engineering building in which the Department of Mining Engineering will have quarters.

INDIA'S MINERAL RESOURCES

The petroleum production of India and Burma in 1897 was only 19,000,000 gallons; in 1908 it had increased to 176,500,000 gallons, and in 1909 amounted to 233,500,000 gallons.

It is well known that India possesses enormous untapped supplies of iron and copper, which only require the necessary enterprise and capital for their exploitation. The Tata Iron and Steel Co. is about to introduce a new era into the mineral and metallurgical life of India, and the time is apparently not far off when this country will be in a position to smelt its own ores with its own coal and fluxes, and not only produce sufficient to supply its own needs, but to export the surplus to other lands. The Tata iron and steel plant is really an American conception and is being pushed to completion under the supervision of American engineers and mechanics and will be equipped largely with machinery made in the United States.

ALABAMA INSPECTORS' WARNING CARD

James Hillhouse, Chief Mine Inspector of Alabama, and his associates, Robert Neill and J. W. Dickinson, got up the following warning card last November and had it posted in conspicuous places at the coal mines. It was so instrumental in diminishing accidents that the consuls and vice-consuls of Austria-Hungary, Russia, and Italy have adopted it for translation, publication, and distribution among miners of those nationalities in other states.

WARNING!

TO ALL MINE EMPLOYES

The subject of mine accidents is attracting a great deal of attention throughout this state. From the loss of life incurred thereby, the suffering cannot be measured. The desolation and want that follow the killed or crippled bread winners call forth much sympathy. In some of these accidents the danger is unforeseen, but a large majority could be avoided if the necessary precautions are taken. This office suggests the following:

That every coal mine worker familiarize himself with the mining laws which are posted at all coal mines.

THE MINER

Don't forget to sound the roof on entering your place to begin a day's work.

Don't forget to sound the roof after each blast.

Don't use short fuse, "skinner backs."

Don't use two different explosives in same hole.

Don't use coal for tamping.

Don't conclude the roof is safe in spite of drummy sound.

Don't take lighted pipe or lamp to your powder box.

Don't fire two holes at the same time.

Don't bore your holes beyond the mining.

Don't hurry in order to get out early.

Don't risk your life to save labor.

Don't forget the miner is responsible for the safety of the laborer.

THE LABORER

Don't go into working place until the miner has examined it and pronounced it safe.

Don't fire blasts for the miner nor in his absence.

Don't disregard the orders of the miner.

Don't forget to retreat to place of safety when blasting.

DRIVERS

Don't ride between cars.

Don't ride on side of cars.

Don't run cars on grades until you know the road is clear below.

Don't forget to call driver boss' attention to bad track.

Don't take door boy away from his post to drive your mule.

DOOR BOY

Don't leave your door.

Don't allow your door to remain open longer than necessary.

Don't play around or run after trip of cars.

ALL EMPLOYES

Don't ride up and down the slope.

Don't pass over danger signals.

Don't roam through old workings.

Don't travel the slope; take the manway.

Don't smuggle dynamite in mines; and report any one you see doing it.

THE MINE FOREMAN

See that every working place is free of gas before employe starts work.

See that all apparatus affecting safety of employes is in good and safe condition.

See that the above suggestions are enforced.

THE TESTING OF MINERS' OIL

*By C. E. Scott, Chief of Testing Department, Fairmont Coal Co.**

In the West Virginia State Mining Laws, there is an act which reads in part as follows: "That only animal, vegetable, or paraffin oil, or other oil as free from the evolution of smoke as a standard cottonseed oil, when burned in a miner's lamp shall be used in any open lamp or torch for illuminating purposes in any coal mine in this state and that kerosene or blackstrap oil or a mixture of kerosene and blackstrap shall not be used in miners' torches for illuminating purposes in any coal mine in this state."

Legal Requirements. Testing for Smoke—Forms of Lamps. Testing Safety Lamp Oil

The law further states the test the oil must stand, giving in a general way the method of making it. The test is based on the specific gravity of the oil, which must not exceed 24° B. scale, and although some of the physical properties of illuminating oils bear a close relation to the specific gravity, thus allowing it to be taken as an indicator, it is necessary to make further tests to determine the efficiency and relative values of various oils. This fact, together with the desirability of establishing specifications for the purchase of oils led to a series of tests both in the laboratory and the mine.

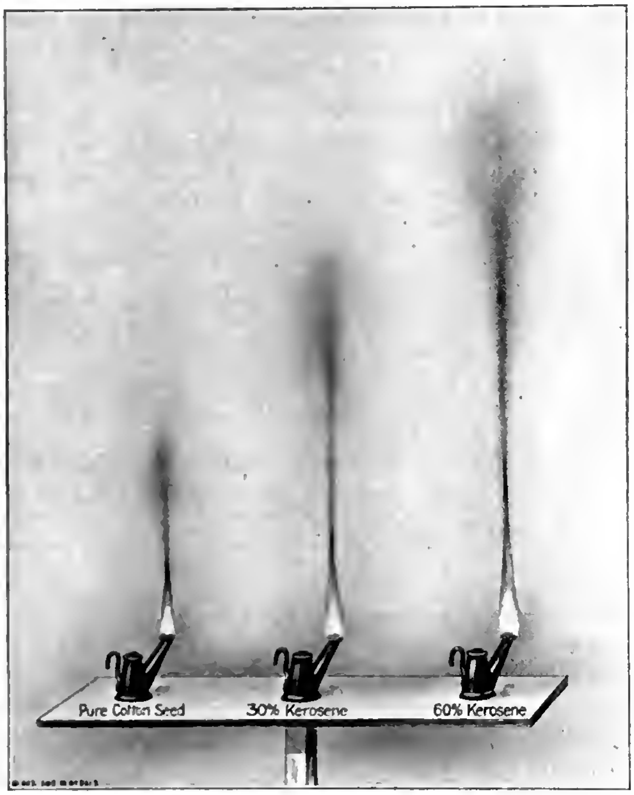

Fig. 1. Effect of Kerosene in Lamp Oil

Samples from mine stores over the entire Fairmont region were tested and analyzed and in the majority were found to be within the state law requirements. Samples of oil being sold by other than coal company stores throughout the Fairmont region were also tested, and in most cases these oils failed to stand the test. Needless to say, many of these oils are adulterated. Oil adulterants are cheap and unfortunately cannot be readily detected, outside of the laboratory.

The following case illustrates one of the difficulties to be met in attempting to prevent the use of inferior oil: A miner, burning oil which he had purchased at a country store, handed his bottle of oil to the district mine inspector and asked him if that oil was all right. The inspector, after shaking the bottle and looking at the oil, passed the opinion that he thought it was. A sample of this oil was later brought into the laboratory and when tested was found to exceed the state law limit in density and to contain 58 per cent. mineral oil. It was an inferior grade of oil highly adulterated. This was a case where both the district mine inspector and the mine boss were taken advantage of, due to the fact that the inspector had not been provided by the state with the necessary apparatus for making a decisive test, and because of the difficulties in making such a test outside the laboratory.

In this connection Section 2 under Oil Regulations of State Mining Law is here given: "Any person, firm, or corporation either by themselves or an agent or employe, which shall sell or offer for sale for illuminating in any mine in this state, any oil or any mixture or compound of oils which does not comply with the tests as prescribed in Section 1 of this Act, shall be deemed guilty of a misdemeanor, and upon conviction thereof shall be fined not less than $25 nor more than $100 for each offense."

Aside from the necessity of carrying out the requirements of the law, there are advantages in supplying the miners with the best oil obtainable, and prohibiting the use of such oils as are usually sold by miscellaneous dealers.

In making the laboratory tests, a standard No. 2 miners' lamp was used for comparing length of flame, smoke evolution, quantity of oil burned and the candlepower of the different oils. The viscosity, congealing point, density and flash points were also determined on each sample.

The viscosity of an oil is the property of the different particles to hold together and at the same time adhere to other bodies. It may be called the "fluidity" or "thickness" of an oil. Oil of high viscosity does not flow so freely as an oil of low viscosity. Viscosity has been the cause of complaint with miners' oil, otherwise satisfactory, as for instance, an oil which gave the following results upon test: Viscosity, 16.2; density, 22° B.; grams oil burned per minute, .2; height of flame, 4 inches. This oil was the cause of dissatisfaction at several of the mines the complaint being that it did not keep lighted on headings and air-courses where strong air-currents were met with, that it was hard to relight, and that the oil did not feed up the wick fast enough. While the flash point of this oil was somewhat to blame for the trouble, it was principally due to the high viscosity.

The congealing point of oil is an important factor in the winter months. It is the temperature at which the oil will solidify, and if this point is too high it is the cause of considerable trouble both to the miner and storekeeper, which results in a loss of time and waste of oil. Although the temperature inside the mines varies but little, there are many cases where roadmen, drivers, motormen, and others, come in contact with air that is almost as cold as that outside, consequently, when buying winter oil there should be a guarantee that it will not congeal at a temperature above 32° F. and it is advantageous to have this point even lower. The winter oil used by the Fairmont Coal Co. shows a congealing point of 21° F. on an average of 22 samples tested. This allows it to be stored and handled in cold places without freezing.

The flash point is the temperature in degrees Fahrenheit at which the oil will flash or ignite. For instance, an oil with a flash point of 300° is one that will ignite when heated to that temperature, if a flame be applied to it. The flash point decreases as the density becomes less; the lighter oils flashing at lower temperatures. Some companies have 300° to 425° F. established as the limit in their specifications for miners' oil, that is, the flash point must not drop below 300° nor exceed 425° F.; the lower limit being applied as a measure of safety; the higher one as a limit at which the oil will readily burn and relight quickly.

The quantity of oil burned for a given length of time is important from the miner's point of view (although it is hard to make him realize it). In trying to comply with the state law,

* A paper read at the winter meeting of the West Virginia Mining Institute.

and also furnish an oil that will give the miner the best results per unit of cost, it is necessary to take into consideration its efficiency. The grams of oil burned per minute depend on th size of the lamp used, the size of the wick, and the length of the wick beyond the spout, as well as the quality of oil. With the first-mentioned conditions remaining constant, the variation in the grams burned per minute depends to some extent upon the density. With a cottonseed oil of high specific gravity the oil burned per minute in a standard No. 2 mine lamp is about .2 gram, while in an oil highly adulterated with kerosene, or a light, highly volatile oil, and of a low specfic gravity, the figure is about .5 gram.

The candlepower of oil naturally bears a close relation to the quantity of oil burned, and to get a comparative figure on different oils as to this property, the candlepower is calculated to candlepower per gram per minute. This takes into consideration the effect of different rates of burning. In making the test of the candlepower, standard photometric candles (12 to a pound) are used, in an ordinary photometer, and the results check very closely. The present specifications call for an equivalent candlepower per gram per minute at 8.

The height of flame is also taken into consideration and is specified in purchasing oil to be between 4 and 5.5 inches with the wick extending ¼ inch beyond the end of the lamp spout, with 12-strand wick. This height has been found to produce the best candlepower with the least amount of smoke, and if the height of flame is limited, the evolution of smoke is to some extent controlled.

In testing miners' oil there is probably nothing of greater importance than the quantity of smoke it gives off while burning. This smoke is, in a measure, indicative of the quality of the oil, as an inferior oil always makes denser smoke and a greater quantity of it, and it has often been noted that the smoke increases as the oil deteriorates in quality. It is this point which guides the mine inspector in his inspection of the oil used at different mines. If the oil gives off an excessive amount of smoke, he becomes suspicious and forwards a sample to the head of the department for test, and it usually develops that the oil is adulterated and not up to the standard required. Aside from the dust and the smoke of the powder, smoke from open lights is the principal cause of air vitiation in the working places of a mine. This is especially noticeable in places where the velocity of the current is very low, and with oil of low grade. An oil to which kerosene has been added (which is common practice in most regions) is the greatest offender in this direction. Its effect on the quantity of smoke produced is shown in Fig. 1.

This is a sketch from a photograph; beginning on the left, the first lamp contains pure cottonseed oil, the next contains 30 per cent. kerosene and the third contains 60 per cent. While it is true that drivers, motormen, and trappers spend most of their time in an air-current of high velocity, oil can be purchased under most severe conditions, and still come up to standard for them, that will burn with a long flame and hold to the wick specifications, with the exception of the density requirement.

The consumption of oxygen due to the burning of oil in a miner's lamp is very small in amount, since it has been figured that only $\frac{1}{17}$ of the total pure air in a mine is required by the miners, horses, and lamps. It is the quantity of smoke given off that causes the greatest vitiation of the mine air.

Although it is difficult to measure the quantity of smoke given off by any particular lamp, the following method, which is similar to the one used by the state mine inspector, gives comparative results and is sufficient for testing miners' oil. This test is made by observation, using pure cottonseed oil as the standard of comparison. The size of lamp, size and length of wick, and the quantity of oil are the same in each case, and length of the smoke pencil on the standard oil is taken as one, and the length of the smoke pencil on the oil tested is relatively greater or less. The lamps are placed in a box with a glass front, and a white cloth, graduated in inches, serves as a background. The limit placed on the smoke is a pencil about 1.5 greater than that of the standard cottonseed oil. This test, however, is unnecessary quite often when other requirements above mentioned are complied with, as they govern to a very great extent, the evolution of smoke.

Apparently the most difficult requirement to meet is the density, which must not exceed 24° B. scale, which corresponds to .913 specific gravity. Of many samples of miners' oil of different kinds submitted by many companies, there has been only a small percentage to come within the limit. Its adoption as part of the specifications of some companies has been due solely to the fact that the State Oil Regulations require it. Miners' oil of excellent quality can be obtained at very reasonable prices, only a degree over the state law limit, but is not purchased because it exceeds 24° B. This test is made at 60° F., and while certain properties do bear some relation to the density, there is no reason, apparent, why this limit should have been placed as low as 24° B. Very seldom has a miners' oil sample been received in the laboratory that does not exceed this point. We have found oils up to 30° B. that were highly satisfactory for use in miners' lamps, being pure unadulterated oils "as free from the evolution of smoke as a standard cottonseed oil." In fact, they were more satisfactory than standard cottonseed oil. The following tests are an example of this.

	No. 1 Cottonseed Oil	No. 2 Colza Oil
Viscosity	18	7
Density	22.0° B.	30.6° B.
Flash point	532° F.	306° F.
Congealing point	22° F.	20.6° F.
Candlepower	1.19	1.44
Flame height	3.5"	4.5"
Grams oil per minute	.17	.19
Candlepower per gram per minute	5.95	7.58
Smoke	small amount	small amount

The report on these two oils from the test given them in the mine is as follows: "Oil No. 2 seemed to be far superior in every way; it made a bright, clear flame, which did not easily blow off of the wick as does oil No. 1, and it made no more smoke." In addition to this it seemed to have fine lasting qualities, as a standard No. 2 miner's lamp, of the Star pattern, burned 1 hour and 35 minutes with one filling, which is at least 15 minutes longer than the same lamp will burn under the same conditions with oil No. 1."

Again, we have an oil that is highly satisfactory and gave the following results when tested: Density, 24.8° B.; flash point, 409° F.; congealing point, 14° F.; oil burned per minute, .4 gram; flame height, 4.5 inches; smoke, small amount; both this oil and the colza are beyond the 24° B. limit, yet they are pure oils and give little or no more smoke on burning, and due to the difference in price as against the standard cottonseed oil, they could be supplied to the miner at much lower price and would give him a more efficient light in every respect, hence are more desirable than the oil that comes within the present limit of the State Oil Regulations. There is an excellent mixed oil, with cottonseed as its base, recently submitted at a price considerably under that of cottonseed, which gave the following results: Density at 60°, 25.0° B.; flash point, 392° F.; congealing point, 16° F.; grams oil per minute, .18; candlepower, per gram per minute, 7.3; height of flame, 5½ inches; smoke, slight.

A trial test was made extending over several months on standard cottonseed oil, and the reports from 41 mines using it were, in effect, that it was of such high density (low Baume) and high flash point as to be very unsatisfactory. The flame would not hold to the wick, the lamp once out was hard to relight, the light furnished was of low candlepower, and the cost was excessive.

The following table serves to give an idea of what may be expected of a standard cottonseed oil when tested:

Viscosity	Density	Candle-power	Grams Oil (Per Minute)	Height Flame Inches	Flash Point
19.3	22.1° B.	1.23	.15	1¾	560° F.
18.2	21.8° B.	1.25	.17	2¼	580° F.
18.0	21.7° B.	1.32	.19	4	587° F.
20.0	22.0° B.	1.34	.18	3½	552° F.
17.5	22.0° B.	1.34	.17	3½	532° F.
18.0	22.0° B.	1.35	.19	3¾	590° F.
17.1	22.3° B.	1.46	.20	3½	562° F.
16.2	22.0° B.	1.54	.20	4	515° F.

If the limit on density as now stated in the State Oil Regulations were raised to 26° B. there would be advantages to the mine owner and the miner, as well as the oil refiner. The miner could then be supplied with an oil of greater illuminating value at a lower cost and there would not be the tendency to mix light burning oils with it, on the part of the miner. We can see no reason why the act governing this should not be changed to read 26° instead of 24°.

Summing up, the present specifications on miners' oil as adopted by the Fairmont Coal Co. read as follows: Density 24° B. or under; congealing point, 24° F. or under; flash point, 300° to 425° F.; flame height, between 4 and 5.5 inches (in No. 2 miners' Star pattern lamp with ¼-inch wick projection, 12-strand cotton wick); equivalent candlepower per gram per minute, 8 or over; smoke, to be light in quantity.

Fig. 2. Miners' Lamps

When a new oil is to be purchased, samples of it are received and tested and unless it comes up to these specifications it is not considered by the purchasing agent. If a purchase is made of an oil that has been found to be all right, each consignment is tested as it is received at the supply department. If it should here fail to come up to the requirements, as stated, it is rejected. It is a rule to test the oil at every mine at regular intervals as well as each shipment received by the supply department.

Lamps.—Using a standard test oil, different style lamps were tested for efficiency, the points considered being the ability of lamps to hold flame under different velocities of air-currents, the candlepower and the amount of oil burnt per hour. The two lamps which gave the best results are standard-size No. 2 lamps, one with a double-wick spout, the other with a single spout and cup at upper end of spout, which is connected to the bottom of the lamp by means of a wire.

These two lamps, shown in Fig. 2, give equally good results. Both have their merits; the outside casing of the double-spout lamp is a protection to the inside tube, keeping it at a uniformly higher temperature and thereby keeping the oil at a temperature which allows it to feed up the wick sufficiently to give the necessary supply, regardless of the temperature of the surrounding air. The wire connecting the cup to the bottom on the other lamp serves the same purpose, and the cup around the top of the spout catches any overflow of oil and keeps the lamp clean.

Safety Lamp Oils.—The Wolf safety lamp is almost exclusively used in this region. Not only is it admirably adapted to the needs of a working lamp but it is a quick and reliable indicator of the presence of firedamp.

The specifications for the naphtha used in these lamps are those recommended by the manufacturer, as follows:

"The naphtha that should be used in safety lamps is a product of a distillation from crude petroleum and must be rectified safety-lamp naphtha and at 15° C. (59° F.) should have a specific gravity of .690 to .730, and below 60° C. (108° F.) (measured in its vapor) no appreciable quantity should be distilled over. At 150° C. (302° F.) all of the naphtha should distill over.

"Poured upon a flat dish, all the naphtha must evaporate completely at common temperature without leaving any petroleum products. Filter paper saturated with naphtha must become perfectly dry in a very short time without leaving any spots which would make the paper appear translucent. Smooth writing paper which has been saturated with naphtha must also become dry in a very short time, so that one can write on it with ink without the ink running on the paper.

"In order to assure a perfect lighting of the lamp by means of an igniting device there must be a sufficient quantity of low-boiling hydrocarbons present, so that at 100° C. (212° F.) (measured in its vapor) at least 73 per cent. and not more than 87 per cent. of its volume will distill over. Heavy hydrocarbons which boil over 150° C. (302° F.) must not exist, as a bright flame, which is an important feature, would be impossible.

"The naphtha must have an aromatic and not a petroleum odor. The candlepower of the naphtha which is supplied should be such that in a properly cleaned and filled Wolf naphtha lamp, giving a flame about 30 millimeters (1½ inches) long, should give at least $\frac{8}{10}$ candlepower. For the determination of the candlepower, a Bunsen photometer is used and the paraffin candle adopted by the Association of German Gas Engineers, giving a flame 50 millimeters (2 inches) long, is accepted as a unit."

In addition to the Wolf safety lamp, the gas inspector of this company used a Chesneau safety lamp, which indicates the presence of firedamp down to .5 of 1 per cent. This is an alcohol lamp in which liquor of the following composition is used: Methyl alcohol (CH_2OH density .8275), 1 liter; copper nitrate, $[Cn(NO_3)_2]$, 1 gram; ethylene bichloride ($C_2H_3Cl_2$), 1 gram.

FRENCH COAL MARKET

No attempt has been made to import American coal into France by way of Rouen, and for the purpose of enabling American producers to consider this question, and to give them a standard for comparing American coals with those most in demand there, the following analyses of British coal are given, together with prices, etc.:

Constituents	Anthracite		Bituminous	
	Highest Per Cent.	Lowest Per Cent.	Highest Per Cent.	Lowest Per Cent.
Fixed carbon	92.30	89.00	72.70	64.70
Volatile matter	4.30	5.50	18.60	25.30
Sulphur	.80	1.50	2.40	2.00
Ash	1.70	2.70	5.50	6.50
Water	.90	1.30	.80	1.50

Bituminous coal for French use is usually brought as "through" coal—what is termed "mine run" in the United States and "tout venant" (all coming) in France—or broken, according to the following sizes: Large, 2⅓ inches; minimum, up to large blocks; cobbles, 2¼ to 3½ or 4 inches; nut, 1¾ to 2¼ inches; small pea, ⅓ to ¾ inch; large pea, ⅜ to ¾ inch; duff, the dust left after extracting the foregoing.—*United States Consular Report.*

FIRING AMMONIUM NITRATE EXPLOSIVES *

The consumption of ammonium nitrate safety explosives is steadily increasing. It is of importance not only in gaseous mines on account of the safety from gas ignition, but also for other blasting purposes on account of the safety in transportation, storage and use. Professor Will, in a lecture delivered before the Austrian Association of Engineers and Architects in the beginning of April, 1910, stated that the consumption of these explosives in Germany has already exceeded that of dynamite. This marked increase is due in some measure to the fact that the majority of German coal mines contain firedamp, and blasting in them is permitted only with safety explosives.

Slow Action of These Explosives Requires Special Igniters to Insure Proper Detonation

In Austria the estimated yearly consumption of ammonium nitrate explosives (ammonal, dynammon, permissible dynammon, progressite, etc.) is in the neighborhood of 1,100,000 pounds. Of this consumption ammonal constitutes by far the largest percentage, as its enormous potential energy offers many economic advantages. Ammonal has also been found to be reliable for blasting in coal mines without firedamp, and with comparatively small charges produces a good fall of lump coal. The consumption in different coal districts, particularly in the Bohemian brown coal (lignite) districts, has already reached 330,000 pounds per annum. For gaseous mines, another variety of ammonium-nitrate explosives must be employed, which is characterized by low explosive temperature and small flame production.

So far only compounds of the carbonite type can compete with the ammonium nitrate in gaseous localities, but it is apparent that the economic advantage is on the side of the ammonium-nitrate explosives; since in the carbonites, which contain on an average 25 per cent. nitroglycerine, the heat production of the nitroglycerine must be reduced by an admixture with suitable substances which do not add anything, or very little, to its potential energy, whereas, the ammonium-nitrate explosives through their principal and main ingredient produce the low temperature necessary.

The conditions for all ammonium-nitrate explosives have become most favorable since the supply of its chief ingredient is assured. Fears of an inevitable crisis in all modern explosives with the exception of the chlorates and perchlorates, which have arisen recently through the impending exhaustion of the Chilian saltpeter deposits and the consequent increase in price of nitric acid, have fortunately proven to be without foundation, since nitric acid can now be produced in unlimited quantities from the atmosphere. Not only nitric acid, but also nitrates have already been produced in this manner in large quantities and put on the market. This assures a rational production of the ammonium-nitrate compounds for the future.

At first considerable difficulty was experienced in the use of all the ammonium-nitrate explosives, through their failure to explode or through burning out of the charge, and from large collars remaining at the bottom of the drill hole. Even now after these compounds have been in use for years, new consumers, who are not well versed in the use of these explosives time and again complain of misfires. However, careful inquiry always shows that this is not due to deterioration or unevenness in the quality of the explosive, but to the use of too weak or poor blasting caps. Deterioration from dampness on account of the hygroscopic nature of ammonium-nitrate cannot very well occur if the explosives are packed carefully and handled with ordinary care. But not only for civil but also for military purposes where the ammonium-nitrate explosives have been in use for a long time for explosive projectile charges, it has been clearly demonstrated that everything depends on the primary ignition, and that poor ignition will produce practically no result, whereas, good ignition can produce a remarkably high maximum. This is a peculiarity of these explosives, and it depends on the chemical and physical properties of its chief ingredient, ammonium nitrate. Whereas the smallest spark is sufficient to completely ignite and explode any quantity of ordinary black powder, and dynamite and kindred explosives can be readily and completely detonated by a sympathetic explosive wave due to a slight mechanical impulse or by heating it too rapidly, the ammonium-nitrate explosives proper act entirely different.

Ammonium-nitrate explosives proper comprise those which contain the latter as chief ingredient, and not merely as adjuvant admixture, as for example ammonium dynamites. The ammonium-nitrate compounds proper require for complete detonation, even in an enclosed space, a very strong initial impulse, since they resist disintegration through the slowness with which they transmit the explosive wave. The easily detonated compounds may be compared to a pyramid resting on its apex which is readily overthrown by a slight blow of a hammer, the ammonium explosives, however, can be compared to a pyramid resting on its base which requires a strong blow to overthrow it.

How is it possible then to develop the maximum energy from the ammonium-nitrate explosives? A few, as dynammon (composed of ammonium nitrate and charcoal), may be completely ignited under special conditions in an enclosed space, by a small initial charge of black powder. This is, however, merely a rapid combustion similar to that of black powder, and its increased energy over the latter depends solely in the increased volume of gas developed by ammonium nitrate.

A true detonation corresponding to the action of dynamite can be produced only with the assistance of a rapidly detonating compound. As dynammon is also suitable for shooting, an ammonium-nitrate powder charge may be ignited in a gun by a suitable black powder ignition, and very good results are obtained, very much superior to the common black powder. But if the same charge should be ignited by a strong fulminate blasting cap, instead of discharging the projectile, the barrel of the gun would be blown to pieces.

Up to the present time, fulminate blasting caps are used almost exclusively as detonators for the ammonium-nitrate explosives. These are composed either of fulminate with a little potassium chlorate or of a mixture of fulminate and trinitrotoluol. The latter is said to increase the efficiency and at the same time diminish the danger from jar and friction. These caps, which are also employed for setting off dynamite, must be fairly large (at least 1 gram No. 6) for the ammonium-nitrate explosives to secure a complete detonation of the charge.

Too much emphasis cannot be laid on the fact that one should not be saving in the size (strength) of the blasting cap. Even for dynamite a No. 6 cap is at present used quite frequently instead of No. 3 which was formerly employed. In England a No. 7 cap is generally used for the ammonium-nitrate compounds but in Germany a No. 8 cap is employed almost exclusively. The last number (with a 2-gram charge) is to be most recommended; larger sizes offer no additional further advantages. The slightly increased cost of the larger blasting caps (the difference in prices between caps No. 6 and No. 8 is about $.01 per 100) is repaid by the better and more certain results and a slight diminution in the weight of the main charge; for larger charges moreover the cost of the blasting caps constitutes merely a small fraction of the total cost of the charge. Since the blasting caps are markedly affected by moisture, care must be exercised in storing them in dry places. In practice deteriorated caps are found much more frequently than one would expect; these are still efficient for dynamite, but not for the ammonium-nitrate explosives.

There is a very good simple test for the blasting caps described in Heyse's book of "The Explosives."

The blasting caps are placed upright on a piece of soft

* Translated from *Zeitschrift fuer das gesamte Schiess-und Sprengstoffwesen*, etc., by W. H. Blumenstein, Pottsville, Penna., manufacturer of the ammonium nitrate safety explosive, "Kanite."

sheet lead 4 millimeters thick, and ignited with a Bickford fuse. From the caliber of the hole and the force with which the fragments are driven in, a comparative picture of the quality of the blasting cap may be obtained.

Since the initial impact is all important for the ammonium-nitrate explosives, great care must be exercised to see that the uppermost cartridge which contains the ignition cap is absolutely fresh and dry. Even if the main charge should have been damp, it can still be set off by a dry ignition cartridge containing a strong detonating cap, whereas, a moist ignition cartridge or weak detonating cap will fail with a perfect main charge.

Another point which must not be lost sight of with the ammonium-nitrate explosives is that the rapidity of detonation (i. e., the rate at which the explosion wave is transmitted through the explosive) increases markedly, particularly in these compounds, with the diameter of the cartridge, and for this reason drill holes of greater diameter (30 millimeters = $1\frac{1}{4}$ inches to $1\frac{1}{2}$ inches and up) are to be preferred. In drill holes of great length and small diameters portions of the charge frequently fail to explode. The lowermost cartridges may be powerfully compressed and become non-inflammable before they can be detonated. For this reason also an ammonium-nitrate explosive charge in a drill hole can rarely be exploded by placing a dynamite cartridge on top of it. On account of the slowness of the ammonium-nitrate compounds, which increases with their density, it is to be recommended to loosen the charge in the ignition cartridge, if the latter has become hard, by simple pressure with the fingers, and not to tamp the main charge in the drill hole, but to place it loosely.

The method of ignition suggested by the French engineer L'Heure, would offer great advantages for all ammonium-nitrate explosives. It consists of a thin lead tube (a few millimeters in diameter) said to be filled with trinitrotoluol which passes through the entire length of the charge and is ignited at its upper end either within or outside of the drill hole by a detonating cap.

This method produces a more rapid and complete detonation of the charge, than could otherwise, on account of its slowness, be accomplished by detonating it from its upper end alone. According to the reports, this method of ignition is said to offer a saving of 20 per cent. in explosives on account of its increased efficiency, and is therefore economical in spite of the increased cost of the fuse. The partial non-ignition of charges in long drill holes would then be entirely prevented.

In the interest of a more thorough utilization of the ammonium-nitrate explosives a complete development and popularization of this method of ignition would be highly desirable.

Electric ignition also has its advantages for the ammonium-nitrate explosives, particularly for use in mines. The peculiarity of most of these explosives to cause no smoke, is particularly well shown in this way. The smoke from the fuse as a rule obscures the observation of its smokelessness. Dynamite it is true also produces little smoke, but it gives rise to poisonous gases.

Whatever the method of ignition employed, whether Bickford or electric fuse, the strength of the detonation, in other words the initial impulse, is decisive for the result of the blast. In the L'Heure ignition also with the trinitrotoluol core, the selection of the detonating cap is of similar importance, since the trinitrotoluol also requires a strong shock for detonation.

It is of interest to give a brief résumé of the development of the methods of ignition and of the industries connected with it.

There was first ignition by means of a blade of straw, which were generally prepared by children, women, or mine cripples. Then came the Bickford fuse, the invention of a simple miner in Cornwall which was a great blessing for safety in blasting and also initiated a number of flourishing factories in different parts of the world. Dynamite produced the detonating caps which greatly increased the sphere of utility of the already existing rifle ammunition factories. The ammonium nitrate explosives called for the larger caps from No. 6 up.

The electric ignition which is closely associated with all methods; viz., black powder, detonating caps, etc., has also made advances, as it permits the simultaneous discharge of several shots in large mines.

The simple and practical Bickford fuse, however, in all probability will never be entirely displaced in the technic of explosives.

COMPENSATING GRADES

Written for Mines and Minerals, by R. Dawson Norris Hall, E. M., Du Bois, Pa.

Compensation for Mine Railroad Sidings—The Increase or Decrease of Grades on Railroad Curves

In railroad language, compensation is the allowance made in a grade to ease the passage of rolling stock over curved track. The curves cause a resistance, which is dependent in amount on the degree of curvature. Such resistance would seem to be measurable with exactitude. As a matter of fact, the tightness of gauge, the shape of the wheel tread, the shape and condition of the rail, the wheel base of the engine and cars, their stiffness and the elevation of the rail, all have their bearing on the allowance so that it is not easy to get an absolutely correct value for all roads and conditions of running. It is assumed between .03 per cent. and .05 per cent. per degree of curve. That is, it is as hard to overcome gravity in pulling up a .03-per-cent. grade on a straight line as to overcome the resistance of pulling the same load around a 1-degree curve on a level if adequate compensation is .03 per cent. The method adopted to ascertain the value of a "compensated grade" or "grade with compensation" is to add to the total rise of the grade a sum equal to .03 or .05 times the total curvature of the track from end to end, totaling the curvature arithmetically without regard to any consideration of the direction of that curvature, right or left. The result thus obtained is divided by the total length of the line in even station lengths of 100 feet, figuring, of course, only that part of the road which it is desired to keep at the same compensated grade.

Considering a road 12,000 feet long having central curve angles of 15 degrees, 30 degrees, and 45 degrees right and 20 degrees, 50 degrees, and 90 degrees left, and having a total rise of 200 feet, the total equivalent grade will be $200 + .03\ (15 + 30 + 45 + 20 + 50 + 90) = 207.5$ feet.

Dividing by the 120 even stations in 12,000 feet we obtain the compensated grade, or 1.729 per cent.

Thus the straight alinements which, on an uncompensated grade, would slope 1.666 per cent., have that slope increased to 1.729 per cent. when compensation is provided for. Suppose the curve above stated as having a 15-degree central angle is 300 feet long. Then the degree of curvature is 5 degrees. The grade on the curve will be therefore $1.729 - .3 \times 5 = 1.579$ per cent. and the resistance on the curve will equal the resistance on the straight line with a grade of 1.729 per cent. for all cars on ascending the grade.

The purpose of this article is not to discuss compensation as practiced in ordinary railroad work but to show under what conditions it should be reversed. The purpose of compensation, as viewed in general practice, is to aid the climbing of a hill by the rolling stock. The assumption is that the loads will be approximately equal both ways, but in mineral tracks this is not usually the case. Under the tipple the movement of the cars is always one way, and the conditions require an equal force to move the cars steadily forward. If any force acts against the action of gravity, such as the resistance of a curve, the grade should be increased at that point to make the net impelling force a constant. If a 1.75-per-cent. grade is needed above the tipple and a 10-per-cent. curve must be constructed

at that point, the grade should be increased to 2.05 per cent. Nor should the needs for increased gravity impulsion over switches be overlooked. This increase of grade at curves may be appropriately termed inverse compensation. Unless watched, some railroad engineers will follow the "practical" rule and make the 1.75 per cent. on the curve a 1.45 per cent. without considering the natural reversal of conditions. It is true that few in the profession would deliberately arrange such a condition, but when scheming out the run-around tracks, there is a risk that the differentiation between them and the loading tracks may be overlooked. No wonder that curved tracks under a tipple are so freely reprobated.

Where the grade of a railroad is about .4 per cent. it is as easy to pull loads down the hill as to pull empties up. When such an even balance can be effected, it would be a pity to spoil it by a miscalculation of the compensation. But first it will be well to calculate this ideal grade which requires equal tractive power to be expended on descending loads and ascending empties. This can best be done by assuming a special but normal make up of train, as follows:

Weight of engine and tender = 220,000 pounds; weight of 40 mixed wood and steel cars = 1,600,000 pounds; total weight of train = 1,820,000 pounds.

Let the required grade be x per cent. Then the gravity resistance $= \text{weight} \times \frac{x}{100} = 18{,}200\,x$.

If the cars once started will move down a grade of .7 per cent. without steam and without increase of speed on a straight track, then the stiffness and rolling resistance together = weight $\times \frac{.7}{100} = 12{,}740$ pounds. The gross resistance will equal $18{,}200\,x + 12{,}740$ pounds. Going down the hill loaded, assuming the cars to carry 100,000 pounds apiece, they will weigh $40 \times 140{,}000 = 5{,}600{,}000$ pounds. Adding the weight of the engine as before, the weight of the whole rolling load will be 5,820,000 pounds. The gravity assistance to motion would overcome a resistance equal to $58{,}200\,x$. The stiffness and rolling resistance together will equal $58{,}200 \times .7 = 40{,}740$ pounds. The resulting resistance to motion to be overcome by the steam in the cylinders will equal $40{,}740 - 58{,}200\,x$. Equating these resistances $18{,}200\,x + 12{,}740 = 40{,}740 - 58{,}200\,x$

$$76{,}400\,x = 28{,}000$$

$$x = \text{about } .366 \text{ per cent.}$$

Thus the grade which makes resistance equal on a track where the load travels all one way and the empties all the other way is .366 per cent. in favor of the load.

The resistance of an empty train being pulled up the grade on a 1-degree curve will be $18{,}200\,x + 18{,}200 \times .7 + 18{,}200 \times .03$. The resistance of a loaded train going down the same grade on a like curve will be $58{,}200 \times .7 + 58{,}200 \times .03 - 58{,}200\,x$. Equating

$$18{,}200\,x + 58{,}200\,x = (58{,}200 - 18{,}200) \times .03 + (58{,}200 - 18{,}200) \times .7$$

$$76{,}400\,x = 1{,}200 + 28{,}000$$

Hence, $x = .0157 + .366$

The first figure in the result is the result of influence of curvature and it will be seen that with an increase of curvature the balanced grade will increase proportionately. Hence, it will be easy to write a series of values of ideal balancing grades for varying degrees of curvature.

When the straight-line grade is less than .366 per cent. in favor of the load the grade should be increased on the curves, but not to exceed the figures for the balancing grade given in the table. This increase is because, on so gentle a grade, the loads are harder to pull down hill than the empties up hill and the net resistances of the loads approach nearer the capacity of the engine than the resistances of the empties.

When the grade is more than .366 per cent. on a straight line and in favor of the load, then the empties are harder to haul up the ascent than the loads down the descent and the grades should be compensated in favor of the empties, the curve grade being reduced, but not to an amount which will make them less than the figures given in the table as the balancing grades for that degree of curve.

BALANCING GRADES FOR CURVES

Degree of Curvature	Balancing Grade. Per Cent.
0	.366
1	.382
2	.397
3	.413
4	.429
5	.445
6	.460
7	.476
8	.492
9	.507
10	.523

and so on.

Where the grade is against the loads, of course the easing of the grade at curves should be provided for in every case.

The calculations are based on certain assumptions regarding equipment, but it will be found that these assumptions might be varied considerably without changing the balancing grades. The weight of the engine for any given even grade is a certain per cent. of the whole train load. The carrying capacity of the cars is a definite multiple of their light weight, though there is, of course, a variation between wood and steel cars, the latter being the lighter.

EXAMINATION FOR ASSAYERS IN BRITISH COLUMBIA

To practice in British Columbia, assayers are obliged to pass an examination and receive a license.

The examination held April 24, 1911, covered the following subjects:

(*a*) A knowledge of the principles of inorganic chemistry.

(*b*) Sampling of ores and furnace products; preparation of sample for assay, including also the melting of gold dust and sampling of bar for assay.

(*c*) Qualitative determination.

(*d*) Assay of gold; assay of copper and lead-copper bullion for gold and silver; also assay for copper, lead, gold, and silver.

Determination of moisture, volatile combustible matter, fixed carbon, ash, and sulphur in coal.

Fire assays of gold, silver, and lead.

Wet and combined wet and fire assays.

Gold and silver by combined method.

Copper by electrolytic, colorimetric, and volumetric (cyanide or other approved) methods.

Nickel by electrolytic method.

Iron, lead, lime, zinc, sulphur, and silica, by any approved wet methods.

The mineralogical determination of a number of simple substances.

Entrance for examinations must be made in writing to the Secretary of the Board of Examiners at least ten days before the date set for beginning of the examination and must be accompanied by the prescribed fee ($15).

A certificate of efficiency in assaying will upon payment of the prescribed fee ($15) be issued to each successful candidate, which certificate shall be considered as a license to practice assaying in British Columbia, and notice is hereby given that only those holding such certificate of proficiency, or license will be allowed to act as assayers in the province, under penalty as provided by the Act. Graduates of certain Schools of Mines, in Canada, Great Britain, and Ireland, may be exempt from examinations and may upon satisfying the examiners as provided in the Act receive such certificate of competency or license, upon payment of the fee ($15). Any additional information desired may be obtained from Herbert Carmichael, Secretary, Board of Examiners, Victoria, B. C.

ANSWERS TO EXAMINATION QUESTIONS

Answered for Mines and Minerals, by J. T. Beard

Note.—The following questions, selected from different examinations, are here numbered consecutively. The examination from which the question is taken and the number of the question are found at the end of each. (See foot-note).

Selected Questions of the Pennsylvania Anthracite Foreman Examinations, Scranton, April 3-5, 1911

Ques. 1.—How would you direct a miner to restand a post that had been dislodged by a blast at the face of a chamber? Q. 3B.

Ans.—First, carefully examine and test the roof about the place where the post stood, taking down any loose portions. Avoid going under the unsupported roof and do not delay the work of resetting the fallen timber. If, however, the condition is hazardous, come out and wait for the roof to fall. In many cases it will be wise to stand one or more posts temporarily for protection, before resetting the fallen timber. Finally, clean up the floor where the post is to stand, and, having measured the height, set up the timber, with a suitable cap above it, and drive the stick to its place.

Ques. 2.—When is a working place in a mine said to be safe? Q. 4B.

Ans.—When the roof is sound or properly timbered, the coal properly mined, and the place thoroughly ventilated.

Ques. 3.—Name the causes that bring about mine caves. Q. 5B.

Ans.—Mine caves are the result of too large a percentage of coal being taken out in the first working of the seam, or the leaving of inadequate pillars for the support of the overlying strata; or attempting to open out and maintain too large an area before drawing back pillars; or the failure to keep the pillars in a lower seam vertically under those in the seam above when working contiguous seams. Mine caves are also sometimes caused by a squeeze or creep, or by a mine fire destroying the roof supports.

Ques. 4.—If the horsepower of an engine operating a fan be 40, while the horsepower on the air is only 28, what is the percentage of useful effect? Q. 6B.

Ans.— $\frac{28}{40} \times 100 = 70$ per cent.

Ques. 5.—If a water gauge of 2 inches passes 15,000 cubic feet of air per minute, in a certain mine, what water gauge will be required to pass 30,000 cubic feet per minute under the same conditions? Q. 7B.

Ans.—For the same mine or airway the water gauge varies as the square of the quantity of air passing; or, in other words, the water gauge ratio is equal to the square of quantity ratio. Therefore, in this case,

$$\frac{x}{2} = \left(\frac{30,000}{15,000}\right)^2 = 2^2 = 4$$

and $x = 2 \times 4 = 8$-inch water gauge.

Ques. 6.—How would you guard against danger from the accumulation of water in abandoned workings? Q. 8B.

Ans.—Drain the workings and inspect them as often as may be necessary to insure safety. If this plan is impracticable, construct dams in all openings leading to the abandoned workings and make these strong enough to withstand any possible head of water that may arise therein. This latter plan, however, does not remove the danger of water blast that may occur in inclined seams.

Ques. 7.—Explain why the flame will not pass through the gauze of a Davy lamp in a quiet atmosphere. Q. 14B.

Ans.—The wire of the gauze absorbs the heat and so far reduces the temperature of the flame that combustion ceases and the flame is extinguished in close proximity to the gauze. The complete extinction of the flame and prevention of its passage through the gauze is made possible by the outflowing gas being divided into minute streams by the fine mesh of the gauze and thus brought into closer proximity to the cool wires.

Ques. 8.—State fully what action you would take in case you found bad roof at the face of a working place in your district. Q. 15B.

Ans.—Promptly order the men out of the place and immediately proceed to make a careful examination to determine whether the roof can be made secure with proper timbering, or there is loose material that must be taken down or allowed time to fall. The men should then be instructed to set the necessary timbers without delay, or sent out of the mine and the place fenced off and marked dangerous till such time as it can be made safe for work.

Ques. 9.—What is the quantity of air passing through a gangway 12 feet wide and 7 feet 6 inches high where the anemometer registers a velocity of 473 feet per minute? Q. 16B.

Ans.—The sectional area of the gangway is $12 \times 7.5 = 90$ square feet, and the volume of air passing $90 \times 473 = 42,570$ cubic feet per minute.

Ques. 10.—How would you proceed to remove a body of firedamp from the face of a chamber 30 feet wide and 6 feet high? Q. 18B.

Ans.—Before taking any steps to dislodge the gas, withdraw the men working on the return of this current and station trustworthy men to guard each entrance to the same. Begin now at the cross-cut where the air enters the chamber and erect a line of canvas brattice, extending from the outby rib of the opening inward towards the face of the chamber. Advance the brattice slowly, giving the current time to carry off the gas at the face. Use safety lamps only and test the condition of the air behind the brattice; in no case permit any one to carry a lamp beyond the end of the brattice. As the face of the chamber is reached the gas should be brushed from the corners and other lodgments.

Ques. 11.—(*a*) What is flushing, in mining? (*b*) How is it done? (*c*) What precautions would you adopt while flushing? Q. 27B.

Ans.—(*a*) Flushing is the process of washing a large amount of waste material into abandoned portions of a mine for the purpose of filling up the void places so that the pillars in the mine can be removed without serious damage to the overlying surface. (*b*) Flushing is accomplished by arranging a conveyer on the surface to conduct the waste material to the head of the shaft or bore hole where it is fed into a column pipe, together with a continuous stream of water, which carries it in suspension to the point in the mine where it is deposited behind a temporary dam. The water then drains from the deposited material into a ditch, which carries it to a basin or sump, from which it is pumped to the surface to be again used in conveying more material into the mine. (*c*) It is necessary when flushing to watch the operation closely to see that the waste material and the water are fed into the pipe in proper proportions to avoid clogging the pipe; also, to change the position of the discharge from time to time, to secure the successful filling of the void places, as desired.

Ques. 12.—What method would you adopt in order to have a continuous flow of air past the face of each working place? Q. 28B.

Ans.—In the room-and-chamber system, commonly used throughout the anthracite region, the air-current should be deflected by temporary brattices erected in each chamber wherever necessary to cause the air to sweep the face. Doors should be replaced by overcasts on main roads wherever practicable, and double doors should be used at all principal points of the main air-current where a door is required.

Ques. 13.—In considering water-gauge pressure how is the number 5.2 obtained? Q. 29B.

Note.—(*A*) Examination, Districts 1, 2, held at Scranton, April 3-5, 1911. *B*) Examination, Districts 4, 5, held at Scranton, April 3-5, 1911.

Ans.—This number represents the pressure, in pounds per square foot, due to 1 inch of water column. It is, therefore, the weight of $\frac{1}{12}$ of a cubic foot of water; or, $62.5 \div 12 = 5.2$, as shown clearly in Fig. 1.

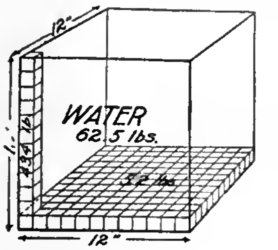

Fig. 1

Ques. 14.—What quantity of air is passing through an airway $6\frac{1}{2}$ feet at the top, $9\frac{1}{2}$ feet at the bottom, and 6 feet high, with an anemometer reading of 300 revolutions per minute? Q. 4A.

Ans.—The sectional area of this airway is $6\,(6.5+9.5) \div 2 = 48$ square feet. The quantity of air passing is, therefore, $300 \times 48 = 14{,}400$ cubic feet per minute, assuming that the reading of the anemometer gives the average velocity of the air-current at this point in the airway.

Ques. 15.—What are the principal causes of mine fires and what precautions would you take to guard against them? Q. 6A.

Ans.—This question is fully answered in reply to Ques. 11, page 734, July, 1910; and Ques. 6, page 52, August, 1910, of Mines and Minerals.

Ques. 16.—(*a*) How many cubic yards of material must be removed in sinking a circular shaft 10 feet in diameter, and 100 feet deep? (*b*) If this shaft was filled with water, how many gallons would it contain? (*c*) What would be the pressure in tons on the bottom of the shaft caused by the weight of the water? Q. 7A.

Ans.—(*a*) The quantity of material excavated would be $100(.7854 \times 10^2) \div 27 = 290\frac{8}{9}$ cubic yards. (*b*) The quantity of water the shaft would hold is $100(.7854 \times 10^2) \times \frac{1728}{231} = 58{,}752$ gallons. (*c*) The weight of the water pressing on the bottom of the shaft is $\frac{100(.7854 \times 10^2) \times 62.5}{2{,}000} = 245.4375$ tons.

Ques. 17.—(*a*) Give a sample report such as you would make after having completed your morning examination of a mine, and finding gas in three places, bad roof in two places, and a fall in an airway sufficient to interfere with the air-current. (*b*) State your duty as mine foreman or assistant mine foreman, after such report is made. Q. 8A.

Ans.—(*a*) Fire boss' report for April 4, 1911, 6:30 a. m.: "I have carefully examined all airways, headings, and chambers in my district and find all working places free from gas and safe, except the following: 1st north, main east, chamber 8, gas; keep out. 1st north, main east, chamber 9, gas; keep out. 1st north, main east, chamber 10, heavy fall of roof and gas; keep out. Also bad roof in chamber 11; keep out. These places are all fenced off and must not be entered. There is also a bad fall at the face of the two blind headings, 5th and 6th north, main east, blocking the cross-cut and checking the air in these headings, which are therefore fenced off. Samuel Jones, Fire Boss." (*b*) It would be the duty of the mine foreman or his assistant, after such report is made, to give his immediate attention to the removal of the dangers mentioned, and to see that the workmen stay out of all places affected till the work is completed and each place has been examined by the fire boss and reported safe. The workmen must be kept out of the return current from the places named while the gas is being removed if much gas is present.

Ques. 18.—What is the ventilating pressure, in pounds per square foot, when the water gauge is $2\frac{3}{4}$ inches? Q. 9A.

Ans.—The corresponding pressure is $2.75 \times 5.2 = 14.3$ pounds per square foot.

Ques. 19.—Explain why the Davy lamp is used by fire bosses and the Clanny lamp by the workmen. Q. 11A.

Ans.—The Davy lamp is sensitive to gas, does not give a good light for working, and is an unsafe lamp in the hands of an inexperienced workman. The Clanny lamp gives a good light, does not flame as quickly as the Davy when exposed to gas, and is or can be protected by a bonnet against strong air-currents.

Ques. 20.—If the run of a mine is 18 cars of coal per keg of powder used, what allowance per car would you make when it is possible to cut only seven cars to the keg; the price of powder being \$1.50 per keg? Q. 12A.

Ans.—The average cost for powder under the two conditions is $\$1.50 \div 18 = 8\frac{1}{3}$ cents per car; and $\$1.50 \div 7 = 21\frac{3}{7}$ cents per car. Hence, the allowance on account of powder to be made is $21\frac{3}{7} - 8\frac{1}{3} = 13\frac{2}{21}$ cents per car, or \$2.75 for every 21 cars of coal mined.

Ques. 21.—In case a fire occurred on the main intake of a mine, endangering the lives of the workmen, by suffocation, state how you would endeavor to rescue them. Q. 14A.

Ans.—Notify the men, at the earliest possible moment, to get out quick by the return airways as far as possible. Reverse, or shut down, or at least slow down the fan, or short circuit the air-current so as to prevent or hinder the smoke and gases of the fire from reaching the men. Ample provision should be made in every mine beforehand to enable the men to reach a safe exit under any conditions that may arise. The danger exists chiefly in the failure to foresee and provide for what may possibly happen in the daily operation of the mine, and the risks assumed are often too great where hundreds of lives are at stake.

Ques. 22.—Name the two gases most commonly found in our mines and state how and where you would expect to find each gas. Q. 3B.

Ans.—Marsh gas or methane (CH_4), and carbon dioxide (CO_2). Marsh gas should be sought with the safety lamp, using some improved type of lamp that will indicate small percentages of the gas and show exactly how much is present in the air. The test for marsh gas should be made at the roof, or at or near the face of rise headings where it may accumulate if the air-current is deficient; also well up on falls and in the accessible portions of disused headings and abandoned workings, and in return airways of gaseous mines. Carbon dioxide may be sought with an open light in low places and dip workings, and in abandoned parts of the mine where the ventilation is slack or not sufficiently strong to carry off the blackdamp as it is formed.

Ques. 23.—What units of work will be absorbed by the frictional resistance of an airway 6 feet square and 1,000 feet long, when the quantity of air passing is 10,800 cubic feet per minute? Q. 11B.

Ans.—The sectional area of the airway is $6 \times 6 = 36$ square feet. The velocity of the air-current is $10{,}800 \div 36 = 300$ feet per minute. The rubbing surface of the airway is $4 \times 6 \times 1{,}000 = 24{,}000$ square feet. The work of friction is then $u = k\,s\,v^3 = .00000002 \times 24{,}000 \times 300^3 = 12{,}960$ foot-pounds per minute.

Ques. 24.—How many cubic yards of coal are there underlying a lot that measures 175 feet long and 55 feet wide, when the vein has an average thickness of 5 feet 9 inches? Q. 12B.

Ans.—The surface area of the lot is $175 \times 55 = 9{,}625$ square feet. Assuming the vein is level its cubical contents underlying the lot is $9{,}625 \times 5.75 \div 27 = 2{,}049.77$ cubic yards.

Ques. 25.—(*a*) What are the dangers attending the use of electricity in coal mines? (*b*) How would you guard against such dangers? Q. 13B.

Ans.—This question is fully answered in reply to Ques. 14, page 53, Mines and Minerals, August, 1910.

來 來

The power required to ventilate a mine varies as the cube of the volumes of air passing. If it requires 25 horsepower to circulate 100,000 cubic feet of air through a mine, what horsepower will be required to pass 200,000 cubic feet? Solving the proposition: $(100{,}000)^3 : (200{,}000)^3 : : 25 : x$, then $x = 200$ horsepower.—*From Jeffrey Mfg. Co. Catalog.*

Allis-Chalmers Co., Milwaukee, Wis., Bulletin No. 1210, Universal Bolter With Vibromotor Drive, 12 pages; Bulletin No. 1524, Price List of Repair Parts for Auxiliary Air Brake Apparatus, 16 pages.

Pulsometer Steam Pump Co., 17 Battery Place, New York, N. Y., Catalog 17, The Pulsometer, 27 pages.

General Engineering Co., Salt Lake City, Utah, Circular Describing Office and Testing Plant, 4 pages.

E. I. DuPont de Nemours Powder Co., Wilmington, Del., Trap-Shooting, 32 pages; DuPont Lesmok, 8 pages; Infallible Smokeless, 12 pages; Circular Describing Sporting Powders.

Merck & Co., New York, N. Y., 1911 Price List, 80 pages.

Gardner Crusher Co., 550 W. 34th St., New York, catalog describing Gardner Crusher, Disintegrator, and Pulverizer, 12 pages.

Saeger Engine Works, Lansing, Mich., Bulletin 39, describing Olds Mine Hoist, 12 pages.

Pennsylvania Flexible Metallic Tubing Co., 1305 Arch St., Philadelphia, Pa., Interlocking Metal Hose for Highest Pressures, 24 pages.

New Inventions

Complete specifications and drawings for any of the following patents can be obtained from the Commissioner of Patents, Washington, D. C., at the following rates:

Single copies	5 cents each
Copies by subclasses	3 cents each
Copies by classes	2 cents each
An entire set of patents	1 cent each

PATENTS PERTAINING TO MINING ISSUED MAY 2 TO MAY 30, 1911, INCLUSIVE

No. 991,017. Hydraulic coal breaker, William Pill, Cowanporth, England.

No. 990,969. Coaling apparatus, Ysidoro Ferrer, New York, N. Y.

No. 990,859. Apparatus for igniting miners' safety lamps, Ernest Arthur, Hailwood Morley, England.

No. 990,860. Apparatus for testing miners' safety lamps, etc., Ernest Arthur Hailwood, Morley, England.

No. 991,317. Ore crusher or grinder, George Johnston, Chihuahua, Mexico.

No. 992,079. Coking furnace, Leland L. Summers, Chicago, Ill.

No. 992,078. Coking oven, Leland L. Summers, Chicago, Ill.

No. 991,667. Hammer drill, Albert H. Taylor, Easton, Pa.

No. 991,677. Ore feeder, Enos A. Wall, Salt Lake City, Utah.

No. 992,092. Ore jig, George H. Williams, Chicago, Ill.

No. 991,695. Apparatus for electrochemical treatment of ores, Tullio Bubola, Luipaardsvlei, Transvaal.

No. 992,684. Coke oven, Laurence P. Palmer, Uniontown, Pa.

No. 992,492. Coke-oven door, Ludwig Carl Flaccus, New York, N. Y.

No. 992,456. Hammer drill, Albert H. Taylor, Easton, Pa.

No. 992,629. Apparatus for dewatering and classifying ores, Randall P. Akins, Denver, Colo.

No. 993,474. Coal-cutting machine, Louis Thomas, Ans, near Liege, Belgium.

No. 993,783. Crusher head, Volney W. Mason, Jr., New York, N. Y.

No. 993,731. Dumping apparatus, Samuel B. Stine, Osceola Mills, Pa.

No. 993,513. Means for withdrawing dust and fumes from zinc or similar furnaces, Emile Dor Delattre, Liege, Belgium.

No. 993,593. Mining machine, William Guernsey, Prosser, Wash.

No. 993,481. Ore and coal jig, Enos A. Wall, Salt Lake City, Utah.

No. 994,023. Ore crusher, Charles O. Michaelsen, Omaha, Neb.

No. 993,451. Treatment of auriferous and argentiferous ores, Alfred Arthur Lockwood, London, England.

No. 993,424. Throttle valve for rock drills, Daniel S. Waugh, Denver, Colo.
